Subjects of the ci group are expected to be much better in judging causal relations between switches and lamps. At first glance, this hypothesis appears straightforward. However, if causal knowledge is learned implicitly in the form of associations between switch-events and lamp-events, it is possible that subjects of the nci group are able to judge some of the relations after they have been debriefed about the causal nature of the material.

As a measure for causal judgment, the median of the 16 absolute deviations between judgments and correct answers was calculated (variable md) for each subject. The ci group was significantly better at judging the causal relations between switches and lamps (ci: $md=27.9$, $s=31.1$; nci: $md=64.7$, $s=25.1$; $t=3.91$, $p<0.01$). This result makes it unlikely that many of the nci subjects had learned associations between switches and lamps implicitly.

Contingency analysis between recognition and completion task

If subjects used exemplar knowledge only, we expect performance in the two memory tasks to be correlated. If, however, subjects used exemplar knowledge and structural knowledge, performance in the two tasks may well be independent from each other. To judge the contingency between two memory tasks, Ostergaard (1992) has proposed a method for estimating the maximum possible memory dependence for a given data set. The method is based on the contingency tables crossing the answers in both tasks. Stochastic independence is shown when there is a significant difference between appropriate measures of the observed contingency and the contingency assuming maximum memory dependence.

The contingency analysis was applied separately for each subject, yielding distributions of observed and estimated values of the joint probability of giving a correct response to both tasks, and of the contingency measure Δp . Analyses with the data collapsed over all

Table 1: Overview over results of the experiment

	Causal interpretation (ci)	No causal interpretation (nci)	Significance
Recognition			
discrimination index	0.46	0.43	ns
response time for hits	2325 ms	1699 ms	**
Completion			
total deviation	21.9	25.3	*
Causal judgment			
median of deviation	27.9	64.7	***
Correlation			
completion – causal judgment	.62***	.21	

Significance levels: *: $p<0.10$ **: $p<0.05$ ***: $p<0.01$

subjects of each condition were conducted to cross-check the results. Both analyses yielded equivalent results.

In the ci group, the observed joint probability of giving a correct response to both tasks equals 0.31, a value lying right between 0.27, the joint probability of the independence model and 0.34, the joint probability of the maximum memory dependence (MMD) model. Although the absolute difference between the value for the MMD and the observed value is rather small, it is still reliable ($t(19)=2.41$, $p<0.05$). The contingency measure Δp also discriminates between the different models. The $\Delta p = 0.22$ observed in the ci group is significantly smaller than the $\Delta p = 0.37$ of the MMD model ($t(18)=2.26$, $p<0.05$).

Things are different in the nci group, where the joint probabilities of the observed data and the MMD model are 0.23 and 0.24, respectively ($t(19)=0.53$, $p=0.60$). The difference between $\Delta p=0.22$ (observed) and $\Delta p=0.23$ (MMD model) is not significant either ($t(19)=0.11$, $p=0.92$).

The result that in the ci group the observed contingency between recognizing states as studied and completing fragments of these states correctly is significantly below the maximum, indicates that different memories have been used for both tasks. In the nci group, the observed contingency between the tasks is almost at its theoretical maximum, indicating that only one type of knowledge was used for answering the items. The interpretation of these results is that both groups use exemplar knowledge in both tasks, but that subjects of the ci group also use structural knowledge, especially in the completion task. This conclusion is supported by different correlations between measures of causal judgment and completion, which are $r=0.62$ ($p<0.01$) in the ci group, and $r=0.21$ (ns) in the nci group.

Discussion

The present experiment confirmed predictions about the differential impact of causal interpretation on memory for states of a simple system. In part, these predictions were derived from a computational model that formalizes a set of assumptions about acquisition and use of two types of knowledge. Exemplar knowledge about system states is assumed to be acquired and used in all tasks, regardless of causal interpretation. With causal interpretation, subjects can additionally learn structural knowledge based on associations between switch events and lamp events (Schoppek, 2001). This knowledge can be used to reconstruct system states in cases where no relevant exemplar can be retrieved from memory. For reasons described above, this type of knowledge was expected to be useful in a causal judgment task and a fragment completion task, but not in a recognition task,

resulting in stochastic independence between recognition and completion in the condition with causal interpretation.

This approach has much in common with implicit learning paradigms. Similar to those paradigms, subjects are presented with material based on a structure they do not know. In contrast to many implicit learning experiments, subjects of the nci group of the present experiment did not learn much about that structure (see the results of the causal judgment task). However, the view that structure is always learned implicitly, as soon as there is one, is not unchallenged. Wright and Whittlesea (1998) argue against the hypothesis that implicit learning is passive and independent of the intentional processes during learning. According to them, this is a misconception resulting from the fact that in most implicit learning experiments there is little or no variation in the learning phases. Wright and Whittlesea provided evidence that even small variations in the presentation of stimuli, or in the induction task can result in differences of what is learned implicitly. Causal interpretation can be viewed as one of these variations that affects processing in the learning phase.

Other examples of the effect that providing additional information about stimuli enhances memory or other kind of performance are found in classification learning (Nosofsky, Clark, & Shin, 1989) or schema acquisition (Ahn, Brewer, & Mooney, 1992). Common to all these examples is subjects' reluctance to use the additional hints. Ahn et al.'s (1992) subjects used the experimentally provided background knowledge only when they were engaged in tasks requiring the active use of that knowledge. Nosofsky et al. (1989) found that even simple rules defining a concept were only used when subjects were explicitly told to do so.

In the group with causal interpretation, the results resemble those typically found in implicit learning experiments. So does the stochastic independence in that group indicate implicit learning? It is not a new claim, but still useful to analyze the acquisition processes, the knowledge resulting from these processes, and the retrieval processes separately (Frensch, 1998), rather than calling the whole thing "implicit learning". Doing so in the present context results in a detailed web of hypotheses. According to the ACT-R model, the processes for acquiring associations between switches and lamps can be characterized as implicit, because associative learning is an autonomous process that occurs without awareness. That does not mean that it is independent from attentional processes. In fact, what associations are learned depends on the sequence in which perceptual or memory elements are focused on. In the Switches & Lamps System, the condition for acquiring useful associations is a processing sequence that focuses on the changes first (i.e. encode the switch

that has changed since the last item, then encode the lamps that have changed, then encode the rest). The assumption that such a sequence occurs more likely in the ci group, whereas in the nci group, subjects adopt other strategies such as processing the images from top left to bottom right, is plausible, although it was not tested empirically. When the critical difference between ci and nci groups lies in the processing sequence of stimuli, one can conclude the testable prediction that differences between the groups should disappear when nci subjects are instructed to focus on changes and are debriefed after the learning phase.

These deliberations are well in line with the view of Wright and Whittlesea (1998), who claim that "the only major difference between implicit and explicit learning may be that consciously knowing that a domain possesses some important structural property can cause one to learn specifically about that property, whereas the processing performed when unaware that such a property exists may focus selectively on less relevant properties" (p. 419).

As a form of subsymbolic knowledge, associations can be viewed as implicit knowledge. In ACT-R, subsymbolic knowledge exerts its influence through activation processes, but is not directly accessible by production rules. The explanatory potential of the subsymbolic level of ACT-R for implicit memory phenomena has also been demonstrated by Taatgen (1999) with a model of word recognition and completion. In his model it is the dynamics of baselevel learning rather than associative learning that accounts for dissociations.

Only at the stage of applying the knowledge a conscious strategy of utilizing the associations between switch events and lamp events is assumed, a strategy of retrieving the most active lamp event with a given switch-turned-on event as cue.

Since the system I used here was a static one, some considerations about the generalization of the results to dynamic systems are indicated. Dynamic systems are characterized by dependence on their own state, which gives them momentum. This is not the case in the Switches & Lamps System. However, similar to dynamic systems, its output variables depend on multiple input variables. The momentum is an important property that makes it hard to handle dynamic systems (Funke, 1993). This might be one of the reasons why subjects typically focus on the relations between input and output variables, often disregarding the output-output relations that establish the momentum (Schoppek, 2002). Thus, from the point of view of many subjects, the Switches & Lamp System can appear very similar to small dynamic systems like the Sugar Factory.

If one accepts "Switches & Lamps" as a model for small dynamic systems, the work presented here questions the common interpretation that controlling

those systems is accomplished with exemplar knowledge only (Dienes & Fahey, 1995; Lebiere, Wallach & Taatgen, 1998). For obvious reasons, proving the sufficiency of this type of knowledge does not prove that human subjects are making do with this type, too. The findings of the group with causal interpretation parallel those of Dienes and Fahey (1998), who found stochastic independence between recognition and a completion task and arrived at similar conclusions. The present experiment extends Dienes and Fahey's approach by demonstrating that without causal interpretation the contingency between these tasks is close to its possible maximum, indicating that in that case only one type of knowledge is used. Moreover, it involves a real dissociation in the sense that the experimental manipulation affected one task (causal judgment, completion), but not another (recognition). It would be interesting to see if a variation of causal interpretation with the Sugar Factory yielded similar results.

Although many of the predictions were derived from a cognitive model, I have as yet not succeeded in reproducing the whole set of results with the model. For example, the present model overestimates discrimination between old and new states. The main reason for this is the simplified assumption that every state is encoded by three chunks in a one trial fashion: One chunk representing all switches, one representing all lamps, and one grouping the two other chunks together. This assumption has to be replaced by an appropriate theory about how humans form chunks from unfamiliar material, such as the competitive chunking theory (Servan-Schreiber & Anderson, 1990), or EPAM successors like CHREST (Gobet & Jackson, 2001). Nevertheless, even when a model does not reproduce all aspects of the data, the cognitive modeling perspective forces the analyst to explicate assumptions on all stages of processing, thus helping to draw a detailed picture of reality that goes far beyond the simple distinction between implicit and explicit learning.

Acknowledgments

I would like to thank Wayne Gray for valuable hints regarding the paradigm, and Nha-Yong Au for carrying out the experiment.

Abstract

In this paper we discuss issues of instructional design with regard to different goals of instruction in the context of learning from examples. Two different approaches for identifying suitable instructional methods are considered: First, a cognitive task analysis is presented that examines problem-solving strategies applicable for solving mathematical word problems from a cognitive-modeling perspective. The second approach is based on a review of empirical findings on designing instructional examples. Together, these considerations lead to the selection of two instructional methods that are expected to foster learning with respect to different goals of instruction. This assumption is tested in two experimental studies presented in this paper.

Problem-Solving Strategies for Mathematical Word Problems: A Cognitive Task Analysis

When considering different options of designing instructional material it is important to take into account which instructional goal is to be accomplished. For example, in the case of learning from examples, this goal could consist in enabling a learner to solve problems that are either rather similar or dissimilar to the instructional examples. For solving such problems a learner needs to possess specific prerequisites (e.g., knowledge, time to perform different strategies). In order to enable the learner to acquire these prerequisites by studying instructional material, an instructional designer needs a precise conception of the prerequisites that are needed and therefore have to be imparted by the material. In order to acquire information on how problems in question can be solved and which prerequisites are therefore needed it is helpful for an instructional designer to perform a cognitive task analysis. This can be done by using cognitive modeling as a method of task analysis, i.e., by constructing computer models to simulate a human problem-solver's behavior based on cognitive theories (Gray & Altmann, 2001).

Cognitive models are characterized by a high precision that is achieved by the necessity of stating explicit and formalized assumptions in order to get running computer models (Zachary, Ryder, & Hicinbothom, 1998). Because of its high precision a cognitive modeling approach allows for a detailed comparison of different problem-solving strategies (Rittle-Johnson & Koedinger, 2001) as well as for the derivation of instructional methods based on the theoretical assumptions which are specified in cognitive models (Pirolli, 1999).

In the cognitive task analysis presented in this paper we examine two different problem-solving strategies applicable for solving mathematical word problems. A strategy can be characterized as a conditional sequence of subgoals and operators that is suitable to achieve a particular goal (cf. Pirolli, 1999, p. 452). This corresponds to the way strategies are usually represented in cognitive models.

Generally, problem-solving strategies can be classified as search-based, example-based, or schema-based, respectively. Search-based strategies like means-end analysis are appropriate to solve puzzle problems like the Tower of Hanoi (cf. Newell & Simon, 1972) which do not presuppose domain-specific prior knowledge (knowledge-lean problems according to VanLehn, 1989). However, more complex tasks (like solving mathematical word problems) require example-based or schema-based strategies that operate on a rather elaborated knowledge base. Example-based strategies use concrete knowledge about example problems and their solutions. Within this group of example-based strategies different strategies can be distinguished that vary in the extent they make use of example information. Compared to example-based strategies, schema-based strategies use more abstract knowledge representable as generalized, automated problem-solving schemata (e.g. Sweller, van Merriënboër, & Paas, 1998). According to VanLehn (1989, p. 545) a schema consists of „information about the class of problems the schema applies to and information about their solutions“ Example-based and schema-based strategies correspond to two main

approaches in cognitive science, that is the similarity-based and the rule-based approach (Hahn & Chater, 1998).

In our task analysis we examined two strategies for solving mathematical word problems (i.e., the *keyword-strategy* and the *situation model-strategy*) by formalizing them as executable computer models within the framework of the ACT-R-architecture (Anderson & Lebiere, 1998). In the following paragraphs the two strategies will be outlined according to their subgoal structures.

- The *keyword-strategy* is an example-based strategy that uses concrete knowledge about examples when working on new problems (cf. Sowder, 1988). The strategy is characterized by *bottom-up* processing based on the mechanism of *principle-cueing* (Ross, 1987). The respective ACT-R-model starts with reading a given word problem in order to reach the top goal of solving it. While reading, a text phrase that contains certain keywords (or very similar expressions) can activate these keywords in memory. This activation process in turn may lead to the activation of those examples in memory that contain the respective keywords. These known examples will be retrieved if their activation is sufficiently high (*reminders* according to Ross, 1989) and will then be used to solve the current word problem by applying the same procedure to it that was used in order to solve the examples.
- The *situation model-strategy* is a schema-based strategy that operates on a more abstract and elaborated knowledge base and relies on *top-down* processing (cf. Reusser, 1990). The ACT-R model of this strategy again starts with reading, but at the same time it interprets a given mathematical word problem. On basis of this interpretation-process a situation model can be constructed which represents the situation described in the text in a compressed form (cf. Kintsch, 1998). This situation model is then interpreted in a mathematical fashion by matching it with domain-specific schemas representing different problems categories and their appropriate solutions. Thus, in this strategy a given word problem can be solved by applying the solution specified in a known schema that is selected and instantiated on basis of the situation model of the word problem.

A *comparative evaluation* of the two strategies by applying their cognitive models to solving word problems yielded the following results: The keyword-strategy is convenient for equivalent test problems. These are characterized by a near transfer distance because they belong to the same problem category as the instructional examples and are embedded within the same cover story (Reed, 1999). In order to solve such problems by using the keyword-strategy only a very limited amount of problem-solving time and a small knowledge base, mainly containing superficial keywords, are necessary prerequisites. For the application of the situation model-strategy on the other hand, more prerequisites are needed, in particular more time for problem-solving and a larger and more elaborated knowledge base. This base includes schemas for problem categories and knowledge on structural features of problems that determine the appropriate solution procedure. These higher demands with regard to time and knowledge, however, are accompanied by a good problem-solving performance in isomorphic test problems.

These are characterized by an intermediate transfer distance, because they belong to the same problem category as the instructional examples, but are embedded within different cover stories (Reed, 1999).

To conclude, the cognitive task analysis demonstrates computationally that the goal of solving a mathematical word problem can be reached by applying different problem-solving strategies. Thereby, these strategies differ in their processing steps as well as in their prerequisites. In the cognitive task analysis, the latter were specified in terms of problem-solving time and knowledge. However, there are also differences between the strategies with regard to their appropriateness in the context of a specific instructional goal — like solving equivalent versus isomorphic word problems. For equivalent problems, the keyword-strategy is convenient whereas the situation model-strategy is more appropriate in the case of isomorphic problems. Therefore, if the goal of instruction consists in enabling learners to solve equivalent problems, the prerequisites for the keyword-strategy should be imparted by the instructional material. On the other hand, if learners are supposed to learn how to solve isomorphic problems, acquiring prerequisites for the situation model-strategy should be the focus for designing instructional materials. Hence, for an instructional designer it is important to consider the instructional goal in order to ensure that the respective prerequisites are imparted in the materials.

When possessing a precise concept of the prerequisites needed in the context of a specific instructional goal the next question that is to be answered by an instructional designer is how these prerequisites can be imparted by the instructional material. Instructional methods that are suitable in the context of the prerequisites of the two specified strategies may be identified by reviewing empirical findings on designing instructional examples.

Instructional Design: Learning from Examples

The advantages of using examples as learning material have been pointed out in many studies (for an overview cf. Atkinson, Derry, Renkl, & Wortham, 2000). It could be demonstrated that studying examples is of great help for knowledge acquisition and that especially multiple examples support schema induction (e.g., Quilici & Mayer, 1996). However, learners may also experience difficulties when learning from examples. In particular, Ross (1987) found evidence that learners face problems in discriminating between *structural features* of an example (which determine its solution procedure) and *superficial features* describing the example's cover story (which are irrelevant with regard to its solution). Some attempts have been made to counteract such difficulties by improving the design of instructional examples. In order to foster the acquisition of structural features by means of instructional design Atkinson et al. (2000) distinguish between modifying intra-example features, i.e., features concerning the format of a single example, and varying inter-example features, i.e., features related to combinations of multiple examples. An instructional method that bears on inter-examples features and that is supposed to direct learners' attention to structural features is the utilization of so-called *structure-emphasizing example combinations* which are contrasted with *surface-emphasizing example combina-*

tions that guide learners' attention towards superficial features (Quilici & Mayer, 1996). Both types of example combinations are based on imparting knowledge on multiple problem categories which are each illustrated by multiple examples. In the case of structure-emphasizing example combinations each example of a particular problem category is embedded within a different cover story whereas the same set of cover stories is used across problem categories (Table 1, left). Surface-emphasizing example combinations on the other hand, are characterized by the fact that all examples of a particular problem category are embedded within the same cover story which varies across different problem categories so that problem categories and cover stories are confounded (Table 1, right).

Table 1: Structure-emphasizing (A) and surface-emphasizing (B) example combinations

	Problem category (PC)			
	PC1	PC2	PC3	PC4
Cover story (CS)	CS1	CS1	CS1	CS1
	CS2	CS2	CS2	CS2
	CS3	CS3	CS3	CS3
	CS4	CS4	CS4	CS4

	Problem category (PC)			
	PC1	PC2	PC3	PC4
Cover story (CS)	CS1	CS2	CS3	CS4
	CS1	CS2	CS3	CS4
	CS1	CS2	CS3	CS4
	CS1	CS2	CS3	CS4

Quilici and Mayer (1996) asked their subjects to categorize new problems after they had studied examples that were either presented as structure-emphasizing or as surface-emphasizing example combinations. A clear superiority of structure-emphasizing example combinations as learning material could be demonstrated for this categorization task.

Structure-emphasizing and surface-emphasizing example combinations seem to be appropriate instructional methods for imparting the prerequisites necessary to apply the two problem-solving strategies discussed. Structure-emphasizing example combinations should help to acquire structural problem features that are required to apply the situation model-strategy which is appropriate for isomorphic problems. On the other hand, surface-emphasizing example combinations should foster the acquisition of (surface-based) keywords that can be used to apply the keyword-strategy that is suitable for equivalent problems. To test this idea we conducted a series of experiments that differ from the studies of Quilici and Mayer (1996) in several respects.

Using an example-based hypertext environment Quilici and Mayer (1996) conducted paper-pencil experiments without measuring the time that was needed to learn with the different example combinations. On basis of our cognitive task analysis we assume that the two sets of example combinations differ with regard to their time demands. The cognitive task analysis supposes an elaborated knowledge base for the situation model-strategy that rests upon structural features and schemata for problem categories. It is expected that the acquisition of such a knowledge base from structure-emphasizing example combinations demands complex cognitive processes. These processes may require more time investment than processes applied to surface-emphasizing

example combinations that result in the acquisition of surface-based keywords. To test this hypothesis we implemented our experiments as computer-based experiments using a hypertext system for learning and problem-solving that allows for the concurrent automatic registration of time spent on each page visited by means of logfiles. As a result, average learning times for the two instructional methods can be determined and compared to each other.

Extending the application area to children The results of Quilici and Mayer (1996) are based on adult subjects. However, the examination of the proposed instructional methods is particularly interesting with children as subjects. The reason is that surface-emphasizing example combinations are a common learning material in mathematical school books regardless of the instructional goals. Therefore, instructional implications will immediately arise if structure-emphasizing example combinations prove superior in the context of a particular learning goal.

Using problem-solving tasks as test problems Whereas Quilici and Mayer (1996) tested the performance of their subjects mainly by administering categorizing tasks, we use problem-solving tasks that vary with regard to their transfer distance. The reason for this modification lies in the assumption that the superiority of an instructional method depends on the goal of instruction that is related to a particular transfer distance. Surface-emphasizing example combinations may enable the keyword-strategy that is appropriate for solving equivalent test problems. Structure-emphasizing example combinations may allow for the situation model-strategy that is superior in solving isomorphic problems. Because it is assumed that the prerequisites for the keyword-strategy are imparted by surface-emphasizing example combinations and the prerequisites for the situation model-strategy are facilitated by structure-emphasizing example combinations, the following results are expected: Studying surface-emphasizing example combinations has a positive impact on solving equivalent problems whereas learning with structure-emphasizing example combinations fosters the ability to solve isomorphic problems. But both instructional methods may be not very helpful if the instructional goal is to solve problems with a far transfer distance, i.e., novel problems that are characterized by a different cover story and by a different problem category compared to the instructional examples (Reed, 1999). This should be the case because both instructional methods do not impart flexible knowledge that is needed to solve novel problems.

Hypotheses

Based on the results of the cognitive task analysis as well as on the review of empirical findings on designing instructional examples we derived three experimental hypotheses about the use of structure-emphasizing and surface-emphasizing example combinations as instructional material. (1) *Time demands*: Learners using structure-emphasizing example combinations for learning need more time to study compared to learners using surface-emphasizing example combinations. (2) *Differential effectiveness*: Learners using structure-emphasizing example combinations perform better

on isomorphic problems as learners using surface-emphasizing example combinations, whereas the latter show better problem-solving results when working on equivalent problems compared to learners using structure-emphasizing example combinations. (3) *Far transfer distance*: There is no performance difference between learners using structure-emphasizing and learners using surface-emphasizing example combinations when working on novel problems.

To investigate these hypotheses we conducted two experiments using the experimental environment BASIC-OPERATIONS that is described in the following section.

Experimental Environment

The hypertext environment BASICOPERATIONS used for experimentation is based on the hypertext-system HYPERCOMB developed by Gerjets, Scheiter, and Tack (2000). BASICOPERATIONS deals with the domain of basic arithmetic operations and is divided into a learning and a test phase.

In the learning phase, a learner is presented with 16 worked-out examples one after another in a fixed order. Four different problem categories are illustrated by four worked-out examples each. A problem category is formed by the conjunction of two different basic operations; illustrated are the problem categories (PC1) addition/multiplication, (PC2) subtraction/multiplication, (PC3) addition/division and (PC4) subtraction/division. However, another classification of the worked-out examples can be made with regard to their cover stories. Each of the 16 examples is embedded within one of four different cover stories whereby each cover story is used in four examples. The cover stories deal with (CS1) a family on a hiking trip, (CS2) a girl getting money, (CS3) a school arranging a sports meeting and (CS4) a boy buying food. The presentation of the instructional examples is blocked according to the problem categories in a predefined sequence, i.e., all four examples of one problem category are presented subsequently before the next problem category is illustrated.

Two different versions of BASICOPERATIONS (german version on the web: karibik.cops.uni-saarland.de/knac/ex2/zypernA_deutsch and [zypernB_deutsch](http://karibik.cops.uni-saarland.de/knac/ex2/zypernB_deutsch)) were used that can be classified as providing structure-emphasizing or surface-emphasizing example combinations according to the manipulation of Quilici and Mayer (1996). In the version with structure-emphasizing example combinations all four examples illustrating one particular problem category differ in their cover stories (cf. Table 1, left); in the version with surface-emphasizing example combinations all examples illustrating one particular problem category are embedded within the same cover story (cf. Table 1, right).

In the test phase, 18 word problems had to be solved one after another in a fixed order. The instructional example combinations were no longer available during testing. According to their transfer distance with regard to the instructional examples presented in the learning phase the test problems comprised equivalent, isomorphic, and novel problems. In order to calibrate the difficulty of the test problems we conducted a baseline study where subjects had to solve the test problems without any instructional information.

Baseline Study

Method

Participants Subjects were 49 third and fourth grade pupils of an elementary school in Nikosia, Cyprus.

Materials and procedure Subjects received a booklet and were instructed to solve the 18 aforementioned word problems one after another as well as 20 simple arithmetic calculations that were used to measure basic arithmetic skills. Subjects received no guidance or instructional support.

Dependent measures One error was assigned for each wrong answer in the simple arithmetic calculations as well as in the word problems.

Results and Discussion

The simple arithmetic calculations yielded an average error rate of 30.7%. With regard to the word problems, the average error rate was 48.6%. This baseline performance indicated that the word problems were sufficiently difficult to solve for the children so that an instructional support might influence the results. Therefore, this set of word problems was used in the following experiments without any modifications.

Experiment 1

Method

Participants Subjects were 44 (mainly) third and fourth grade pupils of different elementary schools in Nikosia, Cyprus, who participated in the study without payment. Average age was 8.3 years. These subjects had not participated in the baseline study.

Materials and procedure At the beginning of the experiment a pretest was administered to measure basic arithmetic skills. The pretest consisted of 10 simple arithmetic calculations and of 5 simple word problems. After that, a subject started working with BASICOPERATIONS on his or her own using a PC. The experiment ended after the subject had solved the final word problem in the test phase.

Design and dependent measures As a first between-subjects variable the example combinations presented as learning material were manipulated (structure-emphasizing vs. surface-emphasizing). As a second within-subjects variable the transfer distance of the test problems was manipulated by assigning equivalent, isomorphic, and novel problems to subjects. As a first dependent variable we measured the error rates in the pretest. For every wrong answer in the simple arithmetic calculations one error was assigned. With regard to the simple word problems a maximum of two errors for each problem was assigned: one error for applying the wrong basic operation and another error for wrong calculations. Pretest errors were analyzed in order to ensure that the two experimental conditions were comparable with regard to their prior arithmetic skills. Furthermore, time spent on processing example combinations in the learning phase

was registered. In the test phase, error rates in the word problems were obtained by assigning one error for each wrong answer (yielding a maximum of 18 errors).

Results and Discussion

The average time spent with working in BASICOPERATIONS over the experimental groups was about 79 minutes, ranging from 44 to 112 minutes. The children had only little experience with solving word problems as reflected by the average error rates in the pretest for both experimental groups with 31.7% for learners in the structure-emphasizing and 38.5% for learners in the surface-emphasizing condition ($t(39) = -1.15$; $p > .20$; two-tailed).

Unexpectedly, there was no significant difference between learners of the two experimental conditions regarding the time spent on the example combinations with an average of 20.2 minutes for learners with structure-emphasizing and 22.7 minutes for learners with surface-emphasizing example combinations ($t(42) = -.85$; $p > .20$; one-tailed). Similarly, with regard to error rates for the word problems, a MANOVA (example combinations \times transfer distance) revealed no main effects nor an interaction (all $F_s < 1$). A comparison of the average error rates for the word problems between subjects from experiment 1 (50.1%) and subjects from the baseline study (48.6%) showed that the instructional materials in experiment 1 had no effects on performance ($t(91) = .26$; $p > .70$; two-tailed). As an explanation for this unexpected finding one might assume that the children were too young to deal with the instructional materials and that those were not appropriate for learners with very low prior knowledge, i.e., for children just starting to learn how to apply basic operations and how to solve mathematical word problems. To examine this assumption we replicated the experiment with older children possessing a higher level of prior knowledge. For practical reasons, this experiment was conducted in Germany.

Experiment 2

Method

Participants Subjects were 51 third and (mainly) fourth grade pupils of different elementary schools in the Saarland, Germany, who participated in the study without payment. Average age was 9.1 years.

Materials and procedure Materials and procedure were the same as in experiment 1. However, the materials were translated from Greek into German.

Design and dependent measures The design was exactly the same as in experiment 1 with example combinations (structure-emphasizing vs. surface-emphasizing) as a between-subjects variable and transfer distance (equivalent vs. isomorphic vs. novel word problems) as a within-subjects variable. As dependent variables pretest errors, learning time, and error rates for the test problems were measured.

Results and Discussion

The subjects in experiment 2 spent an average of about 52 minutes on working in BASICOPERATIONS, ranging from 21 to 81 minutes. With regard to the average error rates in the pretest, subjects in experiment 2 showed a significantly higher prior knowledge (10.1% errors) than those in experiment 1 with 35.0% errors ($t(90) = 8.02$; $p < .001$; two-tailed). For subjects in experiment 2, prior knowledge did not differ between the two groups with 9.6% for learners in the structure-emphasizing and 10.6% for learners in the surface-emphasizing condition ($t(49) = -.35$; $p > .70$; two-tailed).

First, we investigated whether the two experimental conditions of experiment 2 differed with regard to the learning time invested in studying the example combinations. As expected in the *time demands hypothesis*, learners in the structure-emphasizing condition spent significantly more time with the provided example combinations (17.5 minutes) than learners in the surface-emphasizing condition with 12.2 minutes ($t(49) = 1.81$; $p < .05$; one-tailed). This increased time demand can be seen as a result of the more complex processing necessary to learn with structure-emphasizing example combinations compared to less complex processes that are elicited by surface-emphasizing example combinations.

Second, we examined whether there was a differential effectiveness of the two sets of example combinations with regard to equivalent and isomorphic test problems (Figure 1).

Figure 1: Mean error rates [%] as a function of example combinations and transfer distance

A MANOVA (example combinations \times transfer distance) showed no main effect (all $F_s < 1$), but a significant interaction as expected ($F(1, 49) = 4.11$; $MS_e = 1144.91$; $p < .05$). Subjects who studied structure-emphasizing example combinations performed better on isomorphic test problems than subjects who studied surface-emphasizing example combinations whereas this pattern was reversed for the performance in equivalent problems. In this case the surface-emphasizing condition outperformed the structure-emphasizing condition. This finding provides evidence for the *differential effectiveness hypothesis* which assumes a difference of the two instructional methods with regard to their effectiveness depending on the instructional goal, i.e., transfer distance. Thus, to consider instructional goals may be essential when designing instructional materials.

Third, we tested the assumption that none of the two sets of example combinations supports solving novel test problems. As expected, the error rates for novel test problems did not differ between the two experimental groups with an aver-

age error rate of 36.5% for learners in the structure-emphasizing and 34.0% for learners in the surface-emphasizing condition ($t(49) = .30$; $p > .70$; two-tailed). This result provides evidence for the *far transfer distance hypothesis* which assumes that none of the instructional methods is superior in supporting to solve novel problems.

General Discussion

In this paper issues of instructional design were discussed. It could be shown that different set of instructional examples promote the acquisition of different problem-solving strategies and the accomplishment of different instructional goals.

It was argued that instructional goals must be considered when designing instructional materials. In order to specify these goals cognitive modeling as a method of cognitive task analysis was proposed. In the task analysis that was presented in this paper two specific strategies were examined and evaluated. As a result it was argued that problem-solving strategies differ in their prerequisites as well as in their appropriateness in the context of a particular instructional goal. Accordingly, instructional methods that impart the required prerequisites to apply specific problem-solving strategies also differ in their impact on problem-solving performance with regard to different instructional goals.

Based on these considerations two instructional methods, i.e., providing structure-emphasizing or surface-emphasizing example combinations, were examined in two experimental studies. It could be shown that both instructional methods were not appropriate for young learners with very low levels of domain-specific prior knowledge. But for learners possessing higher levels of prior knowledge, both, structure-emphasizing and surface-emphasizing example combinations proved to be appropriate methods to foster learning and problem-solving depending on the current instructional goal.

Abstract

Learning from worked-out examples is of major importance for initial skill acquisition in well-structured domains. In addition, research has provided knowledge in regards to structuring worked-out examples and how to effectively combine self-explanation activity and instructional explanations. The goal of the present project was to develop a computer-based learning environment in which teachers can learn how to use worked-out examples. Examples of favorably and unfavorably designed worked-out examples were the primary source of information for the teachers. The examples (of worked-out examples) were not in themselves worked-out examples if one views them from a design perspective as the (design) solution steps were not given. We have labeled this type of examples "solved example problems." We investigated to what extent learning from such solved example problems could be fostered by self-explanation prompts and by providing instructional explanations. The results of our 2x2 design (80 student teachers) showed that prompting self-explanations in particular had favorable effects. Hence, self-explanations fostered learning not only from worked-out examples but also from solved example problems. Supplementary instructional explanations only partially enhanced learning and at times they were even detrimental.

Introduction

This study applies the results of cognitive science research (i.e., worked-out example and self-explanation research) to the design of a computer-based learning environment. An empirical study about this learning environment, in turn, contributes to the research on example-based learning and self-explanations.

Learning from worked-out examples is of major importance for the acquisition of cognitive skills in well-structured domains such as mathematics or physics (for an overview see Atkinson, Derry, Renkl, & Wortham, 2000). However, worked-out examples do not guarantee effective learning. One moderating factor is the learner's self-explanation activity. Only when a learner actively self-explains the rationale of the worked-out solutions to her/himself will s/he gain an understanding of the solution procedures. Another

factor is the provision of instructional explanations. In the study presented below, teacher students learned in an example-based computer learning environment how to effectively structure and combine worked-out examples. It was intended to foster their learning by the employment of self-explanation prompts and by supplementary instructional explanations.

Learning by Worked-Out Examples

Worked-out examples consist of a problem, solution steps and the complete solution to the problem. Usually they can be found in mathematics and physics schoolbooks. In most cases, a principle or law is introduced in the beginning followed by a worked-out example. The worked-out example shows how the principle can be applied to problem solving. Then, problems to be solved by the students are given.

Learning by worked-out examples is not meant to refer to the short learning phase between the introduction of a principle and problem-solving. It means, instead, that the example phase is prolonged. Several studies have shown that such example-based learning is more effective for skill acquisition than the standard procedure of studying just one example and then solving problems (for an overview see Sweller, van Merriënboer, & Paas, 1998).

Of course, the use of worked-out examples do not guarantee effective learning. Learning outcomes are influenced mainly by (1) the learner's self-explanation activity and the provided instructional explanations and (2) how the learning materials (examples and problems) are structured (cf. Atkinson et al., 2000). These two aspects are discussed in the following sections.

Self-Explanations and Instructional Explanations

The extent to which learners benefit from the study of worked-out examples depends on how well they explain the rationale of the presented solutions to themselves ("self-explanation effect", Chi et al., 1989; Renkl, 1997; Renkl, Stark, Gruber, & Mandl, 1998). It is especially useful to make the "meaning" of specific operations explicit by reifying the relationship between (sub-)

goals and operators or with the principles underlying a specific operation.

Whereas self-explanations are of major importance, research has shown that the effects of instructional explanations are often disappointing (e.g., Brown & Kane, 1988; Chi, 1996). It seems to be more effective to prompt self-explanations than to offer instructional explanations. On the other hand, it has to be taken into account that relying solely on self-explanations also has several disadvantages. For example, at times the learner is not able to self-explain a specific solution step or the given self-explanations are incorrect.

Renkl (in press) developed a set of instructional principles to support the spontaneous self-explanation activity by providing instructional explanations. Two central principles are (1) the priority of self-explanations (instructional explanations should just be used as type of support) and (2) the furnishing of instructional explanations on learner demand. The study of Renkl (in press) showed that such instructional explanations heightened the average learning outcomes.

However, instructional explanations may not only have positive effects. Due to their feedback functions, a specific problem can occur (e.g., Kulhavy, 1977). If feedback containing the correct answer (here: the explanation) is easily available, learners typically reduce their effort in attempting to find the answer on their own. They tend to look up the right answer instead of coming up with the answer themselves – which reduces learning outcomes. Thus, the provision of instructional explanations may reduce self-explanation activities. Alevan and Koedinger (2000) found, in the context of computer-based learning, that in more than 80% of the cases their learners did not use available help which additionally required self-explanation activity. The learners asked directly for the help which contained the final solution.

In summary, self-explanations are of major importance when learning from worked-out examples. Instructional explanations can foster learning but often they do not. What is left open is the question as to what extent the findings on (self-) explanation can be generalized to non-mathematized content areas.

Design of Worked-out Examples

Researchers (e.g., Catrambone, 1996; Mwangi & Sweller, 1998) have suggested that the design of worked-out examples plays a critical role in their effectiveness (intra-example features). For example, featuring sub-goals prominently fosters learning outcomes (Catrambone, 1996). In the present study, we focused on the so-called *integrated format*: Examples are constructed which integrate all sources of information into one source (e.g., diagrams and text). Splitting learners' attention across multiple, non-integrated informational sources causes irrelevant cognitive load and impairs learning (Mwangi & Sweller, 1998; Ward & Sweller 1990).

Beyond the structure of single worked-out examples the combination of multiple examples is of significance for learning outcomes (inter-example features). In general, multiple examples that contain different surface features (e.g. figures, objects) should be used. This aids the learner's ability to recognize the common underlying structure when asked to compare examples.

Often there are two or more different structures to be learned. It is important to emphasize the structural aspects by using very similar surface features for different problem types. Learners frequently do not recognize the difference of the underlying structure because they concentrate on the similarity of the surface features. Therefore, they often choose the wrong solution. Thus, when dealing with different but interrelated problem types, multiple examples should be combined in such a way that the relevant structural features are apparent to the learner (*structure-emphasized example set*). This can be achieved, as stated above, by using different surface features within one problem type and similar surface features between the different problem types (Quilici & Mayer, 1996).

Of course, there are many other example features which influence the effectiveness of learning from worked-out examples, but in the first module of our computer-based learning environment, we implemented only two features: the integrated format and the structure-emphasized example set.

Research questions

Taking into account the current research on learning from worked-out examples, two important questions can be formulated:

(1) How can we teach teachers the knowledge about the effective use of worked-out examples in their classroom? To reach this goal means to bridge research findings into practice and to improve the quality of instruction.

(2) Do self-explanations and additional instructional explanations foster learning when learning from solved example problems, that is, examples that do not provide solution steps but only the problem and the final solution? Such a solved example problem would be, for example, a well-written essay (literature) or the picture of an intriguing mask (arts). So far it remains an open question as to what extent the results of the worked-out example research, which were mainly obtained within the context of learning mathematics and physics, can be transferred to learning by solved example problems in other topic areas.

For addressing the first question we have developed an initial module for a computer-based learning environment. It is the first part of a future web-based learning environment in which teachers can learn how to use worked-out examples in their classrooms. Due to its intended net-based use, not only "objective" learning outcomes were of interest but also the program's acceptance and the perceived learning results. Those

aspects are of major importance when offering a facultative learning opportunity to practitioners. Acceptance is the basis of the usage of the program itself whereas the perceived results are a predictor for its implementation in classrooms.

In this module, future teachers learn about the design of worked-out examples by studying cases of well and poorly designed worked-out examples. It is important to note that the design of worked-out examples is not an algorithmic process with specific solution steps. Therefore, the examples of the program are, as viewed from the teacher's perspective, not worked-out examples (they do not contain any solution steps) but instead solved example problems (there is simply the problem and its solution) (see Fig. 1).

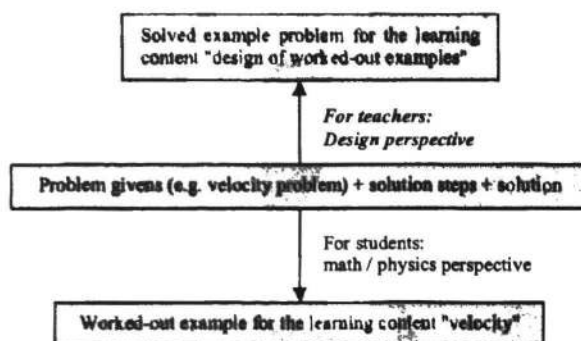

Figure 1: Contents of the learning program from different perspectives

The second research question of this study addresses the effectiveness of self-explanations and instructional explanations when learning by solved example problems: Do self-explanation prompts and additional instructional explanations upon learner demand foster learning?

The following specific research questions were addressed:

1. Is there – as expected – a positive effect of prompting self-explanations on learning outcomes?
2. Is there a positive effect of providing instructional explanations?
3. Do the two instructional means combine additively or non-additively?
4. Do the different instructional treatments influence acceptance and perceived leaning outcomes?

Methods

Sample and Design

80 student teachers from two different colleges volunteered to take part in this study (mean age: 22.3 years; 52 female and 28 male participants). One part of the participants were future teachers in German low-track and medium-track schools ($n = 47$), the other part were future teachers in high-track schools ($n = 33$). The

participants were randomly assigned to the four experimental conditions of a 2x2-factorial design ($n = 20$ in each group). In the experiment, the participants learned in a computer-based learning environment how to effectively design worked-out examples by studying solved example problems (factor 1: prompting self-explanations [with and without], factor 2: instructional explanations [with and without]). In the analysis of the written self-explanations (reactions to the prompts), 6 participants are missing due to technical problems (3 per cell). Technical problems also led to 4 missing values with respect to time-on-task which was recorded as a control variable.

Learning Environment

The program contained a short introduction about learning with worked-out examples. Afterwards examples of worked-out examples or sets of examples were displayed. They were taken from the domains of geometry and physics.

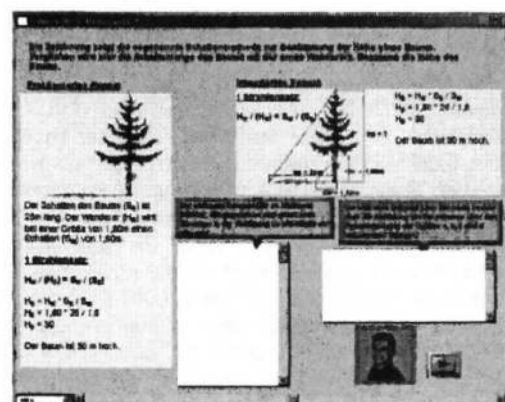

Figure 2: Screenshot of the learning environment

Figure 2 shows a screenshot of the learning environment with a solved example problem with an integrated format. Two worked-out examples were presented to the participants—one required the mapping of different sources of information (graphic, calculation, and text – left side) whereas the other was designed in an integrated format (right side). The self-explanation prompts asked the learners to comment on why one of these two worked-out examples was more favorable. Self-explanations had to be provided to all 13 prompts but their extensiveness (number of elaborations) was self-regulated by the learner. The provided instructional explanations were—in a sense—answers to the self-explanation prompts. They were presented verbally when the learners clicked on a button. The button contained a picture of an expert teacher introduced earlier in the program (see Fig. 2). A "text"-button, which appeared after the acoustic presentation, enabled the learner to view a written explanation. The instructional explanations were

demanding 4.13 times on average ($SD = 3.31$). The frequency of demands did not correlate with learning outcomes. Therefore, this variable was not further considered.

Procedure

The participants worked in individual sessions of approximately 3 hours. In order to provide basic knowledge to allow the participants to be able to understand the solved example problems, an instructional text containing the basic principles of the worked-out example design was given to the participants. Afterwards they studied several solved example problems dealing with an integrated format and structure-emphasized example set in the domain of geometry and physics. The different domains were chosen to foster the transfer of the acquired knowledge. All participants were instructed to think aloud during this period in order to assess (oral) self-explanations (these data have not yet been analyzed). The group with prompted self-explanations had to write down their explanations in note-boxes. During the study of examples, the time spent on different pages of the learning program was registered. After studying the solved example problems, the participants worked on the post-test (learning outcomes). Lastly, the participants filled out a questionnaire regarding the perceived usefulness of the program.

Instruments

Post-test: Assessment of the Learning Outcomes. The first part of our post-test consisted of selection tasks. The participants had to choose one of several given worked-out examples (integrated format) or they had to combine four examples to a structure-emphasized example set. The domains used were geometry, physics (near transfer), and arithmetic (far transfer). For near and far transfer there were three tasks with increasing complexity. Depending on the complexity of the task 1, 4 or 6 points could be achieved (selection part: maximum of 22 points). The second part was a generation task: The participant had to create a structure-emphasized example set in an integrated format. The quality of this task solution was rated by three raters according to specified criteria (e.g., using integrated format in all examples). An entirely correct solution was awarded with 12 points.

Questionnaire. Included in the questionnaire were demographic questions as well as questions concerning the acceptance of the learning environment and the perceived learning results. The items were to be answered on a rating scale from 1 to 6. For the acceptance scale (19 items; e.g., "The content of the program was easy to understand."), we obtained a Cronbach's α of .86. There were four items that assessed the perceived learning results (e.g., "How

would you judge your current knowledge about worked-out examples?"; Cronbach's α : .72).

Written Self-Explanations. In the learning program, the learners in the self-explanation groups were prompted 13 times. The written self-explanations were analyzed using a specifically developed coding system. The main categories were as follows:

(1) *Connection between the design principles of worked-out examples and the solved example problem presented in the program* (e.g., "The variables are written next to the lines, therefore there will be less mapping problems.").

(2) *Linkage to the learning-goals* (integrated format or structure-emphasized example set) (e.g., "A different surface does not automatically require a different solution method.").

(3) *Mathematical content of the solved example problems* (e.g., "In both examples I have to determine the speed.").

(4) *"Side-aspects"* These remarks were correct but did not refer to the learning goals of the program (knowledge about integrated format or structure-emphasized example set) (e.g., "... provided that the second [example in integrated format; comment by the authors] could be drawn clearer.").

(5) *Metacognition* (e.g., "I would have solved the problem in the same way.").

The written reactions to the self-explanation prompts were segmented with the coding categories in mind. Often more than just one elaboration (category) was coded in a reaction to a prompt. The coding categories were distinct and there were no inclusions of segments. A few utterances did not fall into any of the categories (e.g., statements about specifics of the learning program), so they were not taken into account.

We aggregated the codings in two respects. First, all categories were summed up together to an overall score of elaboration activity. The single categories occurred relatively infrequently so that corresponding scores would have not been reliable. Second, the elaborations in reaction to the 13 prompts were aggregated.

Results

Pre-Analyses

In the post-test, a maximum of 34 points could be achieved ($M = 23.20$; $SD = 5.67$). The two subtests (selection and generation) were summarized, due to their similar result patterns and their positive correlation ($r = .31$; $p < .05$).

The post-test correlated significantly with the perceived learning results ($r = .41$; $p < .05$). It did not significantly co-vary with the acceptance scale ($r = .06$; $p > .10$). There was a significant correlation between the acceptance and perceived learning results ($r = .51$; $p < .05$).

The amount of elaborations in the written self-explanations was found to be an important predictor of the learning outcomes ($r = .55$; $p < .05$). There was no significant influence of time-on-task on learning outcomes ($r = .19$; $p > .10$); even in the single subgroups there were no significant relationships between time-on-task and learning outcomes. This pattern in the results indicates that it was not primarily the quantitative aspect of learning (learning time), but the qualitative aspect (elaborations) which influenced learning outcomes. Table 1 summarizes the descriptive results of time-on-task, written self-explanations, acceptance, perceived usefulness, and learning outcomes (posttest).

Effects of Self-Explanation Prompts and Instructional Explanations

In order to determine the effects of our experimental variations, we performed an ANCOVA controlling for the type of student teachers. This variable significantly influenced learning outcomes (low- and medium-track teachers: $M = 22.05$, $SD = 5.76$; high-track teacher $M = 24.83$, $SD = 5.18$; $t(78) = 2.21$; $p < .05$). As the regression slopes of the experimental groups did not differ significantly, the type of student teachers could be used as a covariate.

The analysis of the posttest showed a significant main effect for the prompting self-explanations, that was of medium to high practical significance ($F(1,75) = 8.68$; $p < .05$; $\eta^2 = .11$). There was no significant main effect for the instructional explanations ($F(1,75) = 0.37$; $p > 0.1$). The interaction effect reached the level of significance and was of medium practical significance ($F(1,75) = 4.91$; $p < .05$; $\eta^2 = .06$; see Fig. 3).

Table 1: Means and standard deviations of the experimental groups.

	no self-expl. & no instructional expl.	self-expl. & no instructional expl.	no self-expl. & instructional expl.	self-expl. & instructional expl.
Time-on-task	23.75 (8.82)	46.91 (10.09)	29.64 (9.14)	50.31 (16.76)
Elaborations	—	19.82 (4.51)	—	16.88 (4.51)
Acceptance	4.51 (0.39)	4.39 (0.58)	4.67 (0.65)	4.44 (0.61)
Perceived learning results	3.58 (0.64)	3.98 (0.89)	4.16 (0.77)	3.76 (1.17)
learning outcomes	20.36 (5.46)	25.80 (4.44)	22.75 (5.30)	23.86 (6.29)

As expected, the group without self-explanation prompts and without any instructional explanations performed the worst. Offering instructional explanations fostered learning when self-explanations were not prompted. However, when self-explanations were prompted, supplementary instructional explanations impaired learning. Hence, the most

successful group received prompting of self-explanations, but no instructional explanations.

Figure 3: Interaction between prompting self-explanations and instructional explanations with respect to learning outcomes.

As stated in the introduction, the option to request instructional explanations could reduce self-explanation activities. Indeed, the group with self-explanation prompts and additional instructional explanation did elaborate less than the self-explanations only group (about 17 versus 20 elaborations). The difference was significant ($t(32) = 1.72$; $p < .05$; one-sided).

Did the groups differ in their time-on-task? Table 1 displays remarkable differences between groups (24 minutes versus 50 minutes). There was a main effect of prompting self-explanations ($F(1,72) = 64.91$; $p < .05$), with prompting increasing time-on-task. The main effect of instructional explanations reached only a significance level of 10% ($F(1,72) = 2.93$; $p < .10$). There was no interaction effect ($F < 1$). Even though there were differences in time-on-task between the groups, the experimental effects could not be interpreted as mere time-on-task effects. Firstly, typing the self-explanations per se requires time; secondly, as mentioned above, our analyses showed that the quality and not the quantity of learning activities determined the learning outcomes. However, the results indicated that fostering learning by prompting self-explanations requires additional learning time.

An analysis of the treatment effects on perceived learning results (using the type of student teachers as a covariate; there were no significant differences in the regression slopes of the experimental groups) yielded no main effects in the prompting of self-explanations ($F < 1$) and instructional explanations ($F(1,75) = 1.54$; $p > .10$), but a significant interaction ($F(1,75) = 6.36$; $p < .05$). The two groups with self-explanation prompts showed similar perceived learning results of medium size. The group without such prompts and without instructional explanations evaluated their learning results as low. When only instructional explanations were provided, the participants perceived the highest learning results.

The various conditions did not differ in their acceptance by the learners. There is neither a main effect in the prompting of self-explanations ($F(1,76) =$

1.91; $p > .10$) nor a main effect for instructional explanations ($F < 1$) nor an interaction ($F < 1$).

Discussion

An informal look at the posttest results shows that all student teachers learned substantially about the design of worked-out examples. Hence, we made a significant step towards answering the question as to how to teach teachers knowledge about example-based learning. The extent of learning, however, varied significantly with the experimental conditions. The most effective method was to prompt self-explanations. Instructional explanations were detrimental, at least if they were combined with prompting self-explanations, because they reduced self-explanation activity and thereby the learning outcomes.

Nevertheless, it can be stated that instructional explanations without self-explanation prompts leads to better learning outcomes than leaving the students completely to their own devices. This result is consistent with the findings of Renkl (in press) on the effectiveness of instructional explanations. In Renkl's experiment, no self-explanation prompts were employed.

In contrast to the objective learning outcomes, the highest perceived learning outcomes were found in the instructional explanations-only group. There is an obvious contrast between the real learning outcome and the perceived one. While fostering the learners' own activities objectively leads to the best results, the learners seem to prefer having the explanations presented to them. Apparently, learners do not value instructional measures which require their own activity.

An important consequence of the results presented here is the evident relevance of self-explanation activity for learning outcomes, not only when learning with worked-out examples but also when learning with solved example problems. For this reason the various results concerning the self-explanation-effect are probably transferable to content areas where no worked-out examples can be sensibly constructed. At the same time instructional explanations seem to be less important than self-explanations – equivalent to the results of worked-out example research. However, further research has to be performed using other types of solved example problems.

Looking at the learning processes it is important to note that the mere amount of elaborations substantially predicts learning outcomes. In the near future, the thinking aloud protocols will be analyzed which will give us further insight into the underlying learning processes in the different experimental groups.

The Psychological Implausibility of Naturalized Content

Sam Scott (sscott@ccs.carleton.ca)
Department of Cognitive Science
Carleton University, Ottawa, ON K1S 5B6

Abstract

Conceptual Atomism (CA) is the view that most concepts are represented psychologically as atoms, with no internal structure and CA Atomism on its own is a psychological/semantic theory, but from its inception, it has been mixed up with the separate, meta-semantic project of naturalizing content. I will show that this combined project is forced to end in the self-defeating position of positing non-atomic structures for a large number of concepts. I suggest that a better way out would be to separate the two projects, and allow each to develop on its own.

Introduction

For the last two decades, a number of psychologically minded philosophers have been pursuing a project aimed at naturalizing mental content (Dretske, 1981; 1986; Fodor, 1987; 1990; Millikan, 1984; 1989; 1990). This is a meta-semantic project that seeks an explanation of how meaningful states can arise from non-meaningful ordinary matter. The leading players in this project are also proponents of Conceptual Atomism, the view that concepts are atoms, with no internal structure or necessary relations to other concepts. Conceptual Atomism is a psychological/semantic project, for which the project of naturalizing mental content is supposed to provide a meta-semantics. This combined project – call it Naturalized Conceptual Atomism (NCA) – is still very much a going concern today (Fodor, 1998; Laurence and Margolis, 1999; Margolis 1998; Millikan, 1998; Usher 2001).

The meta-semantic project has a big problem with what I will call 'unacquainted content' (defined below). Proposed solutions to this problem either do not work, or lead to a psychological/semantic position that proponents of NCA have explicitly rejected in the past – namely, that a large number of lexical primitives correspond to complex (non-atomic) concepts. I will look at the three main attempts to naturalize mental content and show how they all either fail or lead to a non-atomic structure for large numbers of concepts. The remedy for this situation, as I see it, is to separate the meta-semantic project from the psychological/semantic project, and let each develop, for the time being, independently of the other.

A Few Definitions

Concept

Following the standard psychological usage, I am using the term 'concept' to mean a sub-propositional mental

representation. (This is in contrast to the standard philosophical usage in which a concept is more like an abstract object.) For the present purposes, I will stick to examples of concepts (mental representations) that are about objects or natural kinds.

Unacquainted Content

Unacquainted content is the Achilles heel of NCA. It is the kind of content that a concept has if its bearer has had no direct experience with the represented object or kind. For example, anyone who has experience with dogs (i.e. almost everyone reading this) will have a normal DOG concept. But most North Americans who have heard of, but never directly experienced, wombats have a WOMBAT concept with unacquainted content.¹

The term 'unacquainted content' also covers many kinds of hypothesized, future or fictional content. For instance the concept, UNICORN, has unacquainted content because the concept bearers could not possibly have directly experienced the nonexistent objects to which it refers.

Nonexistent Object

Nonexistent objects are what concepts with unacquainted content seem to refer to. Maybe nonexistent objects are objects in possible worlds, maybe they have some kind of Meinongian nonexistent being,² or maybe they don't exist at all and references to them are vacuous. I don't intend to take a position on this ontological issue, because the main question of the paper is not whether there are unicorns, but whether there are UNICORNS (atomic representations for unacquainted content).³

The Problem of Unacquainted Content

The main proponents of NCA are Dretske, Millikan and Fodor. All three are engaged in a philosophical project that seeks (a) a naturalized account of (b) external content, and all three tend to assume that (c) concepts are atoms with no internal structure. Their three different brands of NCA differentiate around (d) the special problems posed by misrepresentation. I will briefly discuss these four points of agreement and then I will discuss the differences between

¹ A word in small caps (e.g. WOMBAT) refers to a concept, while a word in single quotes (e.g. 'wombat') refers to a lexical item.

² Alexius Meinong was the German philosopher and psychologist credited with proposing this solution (Meinong, 1904).

³ My hunch is that everyday common sense is pseudo-Meinongian, and therefore my description of a unicorn as a nonexistent object will be perfectly intelligible to all but the most dogmatic readers.

the three proposals, focusing on the special problem posed by unacquainted content.⁴

(a) *A Naturalized Account*. To naturalize content would be to find a coherent story to tell about how the intentional nature of concepts arises from the non-intentional nature of ordinary matter. In practice this has typically meant grounding the meaning of a symbol in some kind of causal or information-bearing relationship between the symbol and the object it represents.

(b) *External Content*. Proponents of NCA follow Putnam (1975) in insisting that there has to be an external or broad component to representational content. Meaning is not (only) in the head.

(c) *Conceptual Atomism*. Dretske, Millikan, and Fodor all make the assumption that concepts and other meaningful mental states must be both syntactically and semantically atomic. A concept simply refers to an object in the world. Semantically speaking, no part of a concept's meaning derives from any relationship it may have with other concepts. Syntactically speaking, if the concept had an internal structure of some kind, it would raise the question of what the individual parts of the structure refer to, and it's doubtful whether that is even a meaningful question to ask in this context. If, for example, DOG is satisfied by all and only dogs because of a causal relationship between DOGS and dogs, then there is just no internal structure in the equation that needs to be explained.

(d) *Misrepresentation*. If the meaning of DOG is just dog, and if DOG gets its meaning in virtue being caused by dogs, what do we do with the fact that sometimes DOG tokens might be caused by things other than dogs? For example, a cat on a dark night might cause a DOG token. If so, this seems to imply that DOG means the same as 'dog or cat on a dark night', which is intuitively wrong. In fact, this "disjunction problem" is much bigger than that. Pictures of dogs can also cause DOG tokens. So can the word 'dog', thoughts about pets, and so on. So the meaning of DOG, on this account, would actually be an infinite disjunction including things like dogs, cats on dark nights, 'dog' tokens, PET tokens, LEASH tokens, and so on. It is in attempting to solve this problem that the three accounts proposed by Dretske, Millikan and Fodor diverge.

Dretske on Misrepresentation

Dretske was the first to formulate a version of NCA built on information theory (Dretske, 1981). According to this approach, a concept C represents some X in the world only if C carries information about X. More specifically, if X and only X causes C then C represents X. The formulation is meant to be counterfactual supporting. So if X and only X

would cause C, then C represents X. Left like this, Dretske's theory suffers from the disjunction problem as badly as any causal theory possibly could – the condition that only X would ever cause C is far too strong to apply to real cognitive agents in noisy environments.

Dretske's proposed solution (Dretske, 1986)⁵ begins by making a distinction between simple and complex organisms. Simple organisms have only one route to a representational state. As an example, he points to marine bacteria that contain magnetic sensors called magnetosomes. These sensors detect the surrounding magnetic field and allow the bacterium to align itself with magnetic north. Since in the northern hemisphere, the lines of the magnetic field are inclined downwards, the bacterium can use the signal from its magnetic sensors to swim upwards or downwards in the water. The bacteria die in the oxygen-rich water close to the surface, so bacteria living in the north are naturally selected to use their sensors to swim downwards (towards magnetic north). If they are transplanted to the southern hemisphere where the field lines incline upwards, they will kill themselves by swimming into oxygen-rich water.

Dretske thinks that simple organisms like the magnetosome bacteria cannot accidentally misrepresent, because the information contained in whatever representations they form is ambiguous. In its natural environment, the bacterium's magnetosome representations reliably causally covary with the direction of oxygen-free water. Hence it is tempting to say that when the bacterium is moved to the southern hemisphere, it begins to misrepresent that direction. But on the other hand, the magnetosome representations also reliably causally covary with the direction of magnetic north, and this does not change no matter where on earth the bacterium is moved to. So on this latter view, it is not a case of misrepresentation that causes the northern bacteria to kill themselves when moved to the south. The magnetosome mechanism still reliably indicates magnetic north, but something else is going wrong inside the organism that causes it to swim in that direction and kill itself. Dretske concludes from this that where there is only one causal route to a representation, misrepresentation cannot occur because the informational content of the representation (i.e. what the representation is *supposed* to mean) is indeterminate. Unless it is possible to unambiguously determine a representation's informational content, it is not possible to determine whether it has been tokened in error.

In more complex organisms, there can be more than one route to a representation. For instance, a human being can detect a hamburger by seeing it, smelling it, tasting it, feeling it, and so on. There are multiple sensory routes that end in the same representation, H. If, on the contrary, one could only detect a hamburger by smelling it, H would reliably causally covary with both the hamburger and the

⁴ Sometimes the term 'misrepresentation' is used to include representations of nonexistent objects and states of affairs as well as representations tokened in error. But nonexistent objects are a kind of unacquainted content. So for my purposes, a misrepresentation is a representation that was supposed to correctly represent an existing object or state of affairs, but, for some reason, failed to do so.

⁵ In later work, Dretske (1988) pursued a different solution that shares more in common with Millikan's approach, discussed below.

odor. So the content of H, on Dretske's story, would be indeterminate. But since there are at least four sensory routes (in a human) to H, the content can be fixed. A token of H caused by seeing a hamburger does not causally covary with the odor of the burger, so the odor can be ruled out as part of H's content. Now we can see how misrepresentation is possible. Any one of the senses can be tricked into causing a token of H when there is no hamburger present, but since the content of H is fixed by the intersection of multiple causal routes, the resulting token H can sensibly be considered to accidentally misrepresent.

Dretske and Unacquainted Content

Information-based NCA of this kind suffers from a big problem with unacquainted content. In Dretske's version, the problem is, in many cases, one of indeterminacy. Take Jay Leno, the host of the tonight show. Like most people with a LENO concept, I have watched him for hours on TV. I know both what he looks like and what he sounds like, so I have two causal routes to my LENO concept. If I ever saw Jay Leno in person, it's reasonable to suppose my LENO concept would be tokened through one or more of these causal routes. So the condition that Leno would cause LENO tokens is satisfied. But the condition that *only* Leno would cause LENO tokens is violated – recordings of Leno also cause LENO tokens. Unfortunately, the multiple causal routes story is no help here because I have only two causal routes to LENO tokens and they would both be engaged whether I saw him live or on TV. It's possible that this problem can be set aside by noting that there is a causal relationship of some sort between the real Leno and the TV Leno, but going down this road will likely produce more problems than it solves. There is a causal relationship between a certain type of bacteria and pimples, but it should not follow, at least in any Conceptual Atomist story, that any part of the content of my PIMPLE concept is a type of bacteria.

The problem gets worse when there is no possibility at all of a direct sensory causal route to a token, as is the case for nonexistent objects like the fictional detective, Sherlock Holmes, or the Second Shooter hypothesized in certain theories about the assassination of John F. Kennedy.⁶ I do know a lot of facts about what these two nonexistent objects are, having heard the conspiracy theory about the Kennedy assassination and read the stories about Sherlock Holmes. But it does not follow that either of these individuals (should they turn out to exist after all) would cause appropriate tokenings in me if I ever saw them, because I have no history of a direct sensory link with them, and therefore no tokens with the appropriate informational content.

⁶ I have no opinion about these theories. Let's just say for the sake of argument that there was no Second Shooter.

Millikan on Misrepresentation

Millikan approaches the problem of misrepresentation from another direction. One way of looking at misrepresentation is to say that it arises when a given representation fails to perform its proper function. For example, if DOG is tokened in response to a cat, we can intuitively say that the mechanism that outputs DOG tokens has failed to do its job properly. The DOG token is only supposed to represent dogs, but it is being tokened (in this case, accidentally) in response to a cat. So all the approaches to explaining misrepresentation within a theory of NCA have in common that they want to find some naturalistic way to describe the proper function of a given representation. Millikan meets this challenge head on by trying to find a teleological solution rooted in the theory of natural selection (Millikan 1984; 1989; 1990; also see Dretske, 1988).

Consider the human heart. Intuitively, we would like to say that its proper function is to circulate blood, but where do we get the authority to say such a thing? Millikan answers that we can say the heart has the function of circulating blood if we can show that's what hearts were naturally selected for. Applying this idea to mental representations, Millikan suggests that we can say that, for instance, DOG refers to dogs if we can show that's what DOG tokens were naturally selected for.

To determine what a representation was selected for, Millikan urges us to focus on the systems within the organism that make use of the representation (Millikan, 1989). For example, the representations produced by the navigation mechanism within a magnetosome bacterium are consumed by some other part of the organism that uses the information to pick the current swimming direction. If we assume that these various mechanisms were selected for their ability to propel the bacterium away from oxygen-rich water, then the proper function of the magnetosome representations must be to represent the direction of such water. So when we transplant the bacterium, it can truly said to be Accidentally Misrepresenting that direction. Millikan's solution has the advantage of allowing us to say what we intuitively want to say about the bacteria – that in normal conditions they represent, and in abnormal conditions they misrepresent.

A tempting way of looking at this solution is that it is the same as Dretske's information-based solution, but with the causal covariation occurring on an evolutionary time scale rather than over the lifetime of a single organism. In fact, Dretske (1981: 234) does toy with the idea of innate representational content produced in just such a way – representations that are selected for the informational content they carry. But reflection on the case of the magnetosome bacteria shows the real difference in the two theories. Recall that Dretske (1986) was forced to conclude that the content of the magnetosome mechanism's representations were indeterminate – there were just too many things the representations causally covaried with to judge which was the 'proper' informational content. Exactly the same argument would apply on an evolutionary scale.

But by focusing on the naturally selected proper function of the representations, Millikan avoids this indeterminacy.

Millikan and Unacquainted Content

As appealing as Millikan's solution to misrepresentation may seem, it has problems with unacquainted content that are at least as bad as those associated with Dretske's approach. As Dretske himself has pointed out (Dretske, 1986), the theory cannot explain representational content for anything that a species either has not encountered during its evolutionary history, or has encountered but had no need or use for. If no member of the species, or any ancestor species, ever encountered a particular type of object, then no part of the organisms that comprise that species could possibly have been selected for the purpose of representing that content. This denies representational content to almost any representation of a nonexistent object, and many representations of real things such as works of art, new pieces of technology, or anything that is recent enough to have played no role in the evolutionary history of the species. Millikan has a problem with unacquainted content on an evolutionary scale.⁷

Fodor on Misrepresentation

Arguably, the most promising version of NCA comes from Fodor (1987; 1990; 1994; 1998). For the last 15 years or so, he has been pushing a theory of Asymmetric Causal Dependence (ACD) theory to explain how an information-based semantics could deal with, among other things, misrepresentation.⁸ In his essay, "A theory of content II", he combines Dretskeian informational semantics (a concept *C* means *X* if it's a law that *X*'s cause *C*'s) with an asymmetric dependence condition (*Y*'s that cause *C*'s only do so because *X*'s cause *C*'s and not vice versa). This takes care of misrepresentations such as cats on dark nights causing DOG tokens (this state of affairs is dependent on dogs causing DOG tokens but not the other way around), and it is also extendible to explain various kinds of "robust" tokenings (non-*X*-caused *C* tokenings that are nevertheless not error cases – for instance, DOG tokens that are caused by pictures of dogs or thoughts about leashes).⁹

⁷ It could be objected that the representation of hypothetical or nonexistent things *in general* is very useful, and thus could have been selected for. But Millikan's theory is supposed to provide an explanation for the specific content of specific representations, and this is what it fails to do for unacquainted content.

⁸ Lately, Fodor (1998) prefers to talk about concept acquisition as a process of "locking on" to a relevant property. The new formulation addresses some concerns about nativism and ontology, but Fodor is clear that however locking on works, the meaning of the resulting concept is still grounded in an informational relationship, and ACD remains his most mature attempt to characterize that relationship.

⁹ Note that I am actually describing what Fodor (1990) called the "pure" version of ACD. He also suggests the possibility of a "mixed" version in which he adds the condition that *C* must have actually been caused by *X* at least once. This mixed version will obviously fail for unacquainted content, so I will only deal with

Fodor and Unacquainted Content

The problem of unacquainted content for pure ACD is immediately apparent, particularly for nonexistent objects. For example, how can non-unicorn-caused tokenings of UNICORN be asymmetrically dependent on unicorn-caused tokenings when there are no existing unicorns? Fodor thinks that this objection can be answered, by reminding us that, like Dretske, he is telling a nomic story:

It can be true that the property of being a unicorn is nomologically linked with the property of being a cause of UNICORNS even if there aren't any unicorns... There wouldn't be non-unicorn-caused UNICORN tokens but that unicorns would cause UNICORN tokens if there were any unicorns. (Fodor, 1990, p101, italics removed and single quotes changed to small caps for consistency).

Fodor has been attacked on the unicorn front before. For instance Baker (1991) constructed a detailed argument based on unicorns and "shunicorns" (a creature of her own design) that requires us to speculate about which of various possible worlds containing unicorns and/or shunicorns is "closer" to our own. If your mind boggles at this kind of talk, I will now offer what I hope is a slightly simpler explanation below for why unicorns are a big thorn in the side of the pure version of ACD.

In this unicorn-free world, all valid UNICORN tokenings must be robust tokenings – they are caused by things other than unicorns. The acquisition of the concept UNICORN in the absence of unicorns comes from exposure to representations (visual or verbal) of unicorns. Having learned about unicorns from books and stories, if a unicorn suddenly popped into existence in front of you, it would likely cause a UNICORN token. So we have two valid causal routes to UNICORN tokens: one from representations of unicorns, and one from possible real unicorns that you might encounter in the future (if unicorns began to exist). To apply ACD, we have to know what would happen if we broke either of these two causal links. Would breaking the causal link between future unicorns and UNICORN tokens break the link between representations of unicorns and UNICORN tokens? My intuition is that this scenario doesn't even make sense, but suppose for the sake of argument that breaking the unicorn/UNICORN link would break the representation/UNICORN link. Then UNICORN tokens are causally dependent on (future) unicorns.

But what would happen if we broke the causal link between representations of unicorns and UNICORN tokens? According to ACD, if UNICORN is to mean unicorn, then this should not affect the causal link between future unicorns and UNICORN tokens. But it obviously does. In a world without unicorns, if you don't learn about them from representations of them then you don't learn about them at all. This means that if a unicorn suddenly popped into existence in front of you, you wouldn't know what it was. Maybe it would cause tokens of HORSE, HORN or whatever,

pure ACD here. And to be fair, Fodor (1994: Appendix B) has made it pretty clear that he doesn't think much of the mixed theory anyway.

but it wouldn't cause a UNICORN token because you wouldn't have one for it to cause. So in the best case, causal dependence runs both ways and ACD doesn't apply. In the worst case (where you don't buy the story about breaking the link between future unicorns and UNICORN tokens) ACD runs in the wrong direction and UNICORN ends up having representations of unicorns as its content. But this must be false – UNICORN has unicorns as its content.¹⁰ Notice that you can run exactly the same argument for any type of unacquainted content, such as my LENO concept. Tokenings of LENO in the presence of Leno are causally dependent on tokenings of LENO in response to representations of Leno.

There is a way out of this trap for an extreme radical nativist. Fodor (e.g. 1998) entertains, though he does not endorse, the possibility that we are born with a stock of atomic concepts waiting to be triggered by the right sort of content-fixing experiences. Applying this idea to unacquainted content, if we all have built-in UNICORN token types that just need to be "triggered" somehow, then maybe our first encounter with a unicorn would cause a UNICORN token after all. Of course we wouldn't have a word for this token, but that is irrelevant. So ACD would be satisfied by assuming that we are born with a lifetime supply of tokens that already have their nomic triggering conditions fixed.

But radical nativism is not a popular option in cognitive science. Though Fodor correctly points out that whether (or to what extent) nativism is true is an empirical question, it seems very unlikely to most researchers that the empirical facts will bear the theory out. Furthermore, if the project is to naturalize content, then all radical nativism does is open up new questions. We are now owed a naturalistic account of how it can be the case that an individual is born with a large stock of mental states that already have the appropriate nomic connections. Given the problems with both Dretske and Millikan's evolutionary accounts, it seems unlikely that such a story is forthcoming. Without the story, all we have reduces to the statement that UNICORN means unicorn because it has a set of properties that causes it to mean unicorn.

The Non-atomic Way Out

All three attempts to construct a theory of NCA seem to fail for unacquainted content. However there is still a way out that is consistent with a slightly weakened version of Conceptual Atomism. This solution, proposed by Fodor (1990: 124) and Dretske (1981: 222, 230) is to allow some concepts to be non-atomic, structured entities built out of atomic components.¹¹ So UNICORN, LENO, and so on actually

unpack into phrasal entities in the language of thought, assembled out of primitive atoms. That is, they are *definitions*.¹² Fodor fails to provide any serious defense of the position, except to state that he thinks the situation in which a complex concept would be required is "*very, very rare*" (1990:124, his italics). Dretske proposes the same solution, but like Fodor, balks at defending it: "I hope [the compositional solution] is sufficiently plausible not to *need* argument" (1981:222, also his italics).

But contrary to Fodor, concepts with unacquainted content don't seem to be particularly rare at all. And contrary to Dretske, the definitional solution does need an argument, having been judged implausible, at least as a general account of conceptual structure, by a wide consensus of Cognitive Scientists.¹³ Almost any standard account of the recent history of empirical research into conceptual structure begins with a recounting of the demise of so-called definitional theories (e.g. Komatsu, 1992; Laurence and Margolis, 1999; Smith and Medin, 1981). The most commonly cited reasons for abandoning of a definitional account of conceptual structure are that: a) there is a widespread consensus that most concept words of any interest are not rigorously definable (see Laurence and Margolis, 1999); b) no attempt to find psychological data that might reveal a definitional structure for simple lexical items has succeeded (e.g. Kintsch, 1974); and c) the well-established psychological phenomenon of typicality ratings, or "goodness of example" effects (e.g. Rosch, 1973) is extremely difficult to account for within a definitional theory (see Smith and Medin, 1981).

Conclusion: A Better Way Out?

Dretske, Millikan, and Fodor have no solution to the problem of unacquainted content, unless we take one of two rather unpalatable options: a) accept a radical concept nativism in which tokens like UNICORN are an innate part of our psychological make-up; or b) accept that many concepts, including UNICORN, WOMBAT, LENO, and so on must have a definitional structure. Nobody seems wants to take option (a) seriously, and it begs the question anyhow, so we're left with option (b), which not only has no empirical support, but also contradicts the whole spirit of the Conceptual Atomist enterprise. What do we do now?

Recall that there are at least two projects here: the meta-semantic project of naturalizing content, and the psychological/semantic project of Conceptual Atomism. The first project is stalled by the problem of unacquainted content, and in attempting to save itself, has wreaked havoc on the second project. My suggestion is that we do not accept this conclusion, and that we separate the projects from now on. Let those interested in the meta-semantic

¹⁰ There is a persistent notion that UNICORN must refer to an idea or to a representation. But a unicorn is not an idea or a representation; it's an animal that looks like a horse with a horn on its head. Ideas and representations are not animals and they have neither heads nor horns. So ideas and representations are the wrong sorts of things to serve as the content for UNICORN.

¹¹ Fodor proposes this (somewhat apologetically) only for cases of nonexistent objects, but it is easily extendible to any unacquainted content.

¹² "... the idea that many terms express concepts that have internal structure is tantamount to the idea that many terms have definitions." (Fodor, 1981: 289)

¹³ Ironically, this consensus includes Fodor himself (e.g. Fodor, 1998; Fodor, Fodor and Garrett, 1975; Fodor, Garrett and Walker, 1980).

problem try to solve it on its own terms, and leave Conceptual Atomism to develop on its own. That way Conceptual Atomism can be consistent with itself in claiming that UNICORN and WOMBAT are atomic, just like DOG and COW. This is essentially the Language of Thought hypothesis (Fodor, 1975) with a referential semantics, but without the causal-historical meta-semantics. UNICORN refers to unicorns, but how, exactly, it comes to do that is an issue to be resolved (or not) by the separate project of meta-semantics.

I suspect that there will be some skepticism as to whether Conceptual Atomism can survive without its accompanying meta-semantic theory. Therefore, I will end with two reasons why I think that it can.

1. *No competing theory is tied to a similar meta-semantic project.* For example, neither the prototype theory nor the theory-theory of concepts attempts to say anything about how meaning arises from non-meaningful stuff. Neither do most modern versions of the definitional theory. And, after all, why should they? At this early stage, a psychological/semantic theory should be judged on its own merits, not by standards set at some other level of analysis.

2. *Conceptual Atomism is still a decent theory even without the meta-semantic project.* There is no psychological evidence for definitional structure, and the evidence that drives the prototype and theory theories can be accounted for within Conceptual Atomism – the former by supposing that typicality effects arise from a separate categorization mechanism, and the latter by supposing that people do have theories that guide their behavior, but that these theories are *about* the concepts they involve, rather than being *constitutive* of them. And above all, Conceptual Atomism is arguably one of the most natural fits to the computational theories of mind that are still so popular.

Abstract

Pearl (2000) offers a formal framework for modeling causal and counterfactual reasoning. By virtue of the way it represents intervention on a causal system, the framework makes predictions about how people reason when asked counterfactual questions about causal relations. Four studies are reported that test the application of the framework to deterministic causal and conditional arguments. The results support the proposed representation of causal arguments, especially when the nature of the counterfactual intervention is made explicit. The results also show that conditional relations are construed in different ways.

Introduction

Many questions are decided by causal analysis. In the law, issues of negligence concern who caused an outcome and, at least under common law, the determination of guilt requires evidence of a causal chain leading to a crime. Evidence that might increase the probability of guilt (e.g., an accused's race) is impermissible if it doesn't support a causal analysis of the crime. Some legal scholars (Lipton, 1992) claim that legal analyses of causality are in no sense special, that causation in the law derives from everyday thinking about causality. Causal analysis is just as prevalent in science, engineering, politics, indeed in every domain that involves human prediction and control.

Causal analysis is often difficult because it depends not only on what happened, but also on what *might* have happened (Mackie, 1974). Thus the claim that A caused B will often imply that if A had not occurred, then B would not have occurred. Likewise, the fact that B would not have occurred if A had not often suggests that A caused B.

This explains a fundamental law of experimental science: Mere observation can only reveal a correlation, not a causal relation. That's why causal induction requires manipulation, control over an independent variable such that changes in its value will determine the value of the dependent variable whilst holding other relevant conditions constant. Everyday causal induction has these same requirements. Causal inductions in everyday contexts are aided by manipulation of potential causes, by people *intervening* on the world rather than just observing it (the conditions favoring intervention are spelled out in Pearl, 2000; Spirtes, Glymour, & Scheines, 1993).

If we already have some causal knowledge, then certain causal questions can be answered without actual

intervention. Some of those questions can be answered through mental intervention, by imagining a counterfactual situation in which a variable is manipulated and determining the effects of change. People attempt this, for example, whenever they wonder "if only..." (if only I hadn't made that stupid comment... If only my data were different...).

Pearl (2000) offers a causal modeling framework that covers such counterfactual reasoning. The framework makes predictions about how people reason when asked counterfactual questions about causal relations. Pearl's analysis extends to relations of probabilistic causality but this paper is limited to studies of deterministic arguments. Before describing those studies, we briefly review the relevant aspects of Pearl's analysis.

Observation vs. Causation (Seeing vs. Doing)

Seeing

In general, observation can be represented using the tools of conventional probability. The probability of observing an event (say, that a logic gate is working properly) under some circumstance (e.g., the temperature is low) can be represented as the conditional probability that a random variable G, representing the logic gate, is at some level of operation g when temperature T is observed to take some value t:

$$\Pr\{G = g|T = t\} \text{ defined as } \frac{\Pr\{G = g \& T = t\}}{\Pr\{T = t\}}.$$

Conditional probabilities are symmetric in the sense that, if well-defined, their converses are well-defined too. In fact, given the marginal probabilities of the relevant variables, Bayes' rule tells us how to evaluate the converse:

$$\Pr\{T = t|G = g\} = \Pr\{G = g|T = t\} \frac{\Pr\{T = t\}}{\Pr\{G = g\}}. \quad (1)$$

Doing

To represent action, Pearl proposes an operator *do*(•) that controls both the value of a variable that is manipulated as well as a graph that represents causal dependencies.

$do(X=x)$ has the effect of setting the variable X to the value x and also changes the graph representing causal relations by removing any directed links from other variables to X (i.e., by cutting X off from the variables that normally cause it). For example, imagine that you believe that temperature T causally influences the operation of logic gate G , and that altitude A causally influences T . This could be represented in the following causal diagram:

Presumably, changing the operation of the logic gate would not affect temperature (i.e., there's no causal link from G to T). We can decide if this is true by acting on the logic gate to change it to some operational state g and then measure the temperature; i.e., by running an experiment in which the operation of the logic gate is manipulated. We could not in general determine a causal relation by just observing temperatures under different logic gate conditions, because observation provides merely correlational information. Measurements taken in the context of action, as opposed to observation, would reflect the probability that $T=t$ under the condition that $do(G=g)$:

$$\Pr\{T = t | do(G = g)\}$$

Obtained by, first, constructing a new causal model by removing any causal links to G :

The rationale for this is that if I have set $G=g$, then my intervention renders other potential causes of g irrelevant. I am overriding their effects, so I should not make any inferences about them. Now I can examine the probability distribution of T in the causal graph. But in doing so, I should not take into account the prior probability of g , because I have set its value, making its value certain by virtue of my action. Because the do operation renders T and G probabilistically independent, the result is that:

$$\Pr\{T = t | do(G = g)\} = \Pr\{T = t\}.$$

The do operator is used to represent experimental manipulations. It provides a means to talk about causal inference through action. It can also be used to represent *mental* manipulations. It provides a means to make counterfactual inferences by determining the representation of the causal relations relevant to inference if a variable had been set to some counterfactual value.

Do we "do"?

Consider the following Causal Argument (1) in which A , B , C , and D are the only relevant events:

- A causes B .
- A causes C .
- B causes D .
- C causes D .
- D definitely occurred.

On the basis of these facts, please answer the following 2 questions:

- i. If B had not occurred, would D still have occurred? ____ (yes or no)
- ii. If B had not occurred, would A have occurred? ____ (yes or no)

Pearl (2000) gives the following analysis of such a system. First, we can graph the causal relations amongst the variables as follows:

You are told that D has occurred. This implies that B or C or both occurred, which in turn implies that A must have occurred. A is the only available explanation for D . Thus, all 4 events have occurred. When asked what would have happened if B had not occurred, we should apply the do operator, $do(B = \text{did not occur})$ with the effect of severing the links to B from its causes:

Therefore, we should not draw any inferences about A from the absence of B . So the answer to the counterfactual question ii. above is "yes" because we already decided that A occurred, and we have no reason to change our minds. The answer to counterfactual question i. is also "yes" because A occurred and we know A causes C which is sufficient for D .

Other theories of propositional reasoning, mental models theory (Johnson-Laird & Byrne, 1991) and any theory based on logic (e.g., Rips, 1994), don't really make predictions in this context because the argument uses causal relations and therefore lies outside the propositional domain. The closest they can come is to posit that causal relations are interpreted as material conditionals (an assumption made by Goldvarg & Johnson-Laird, 2001). To see if such an interpretation of Causal Argument (1) is valid, we can consider Abstract Conditional Argument (1):

- If A then B .
- If A then C .

If B then D.
If C then D.
D is true.

The corresponding questions were:

- i. If B were false, would D still be true? ____ (yes or no)
- ii. If B were false, would A be true? ____ (yes or no)

The causal modeling framework makes no particular prediction about such an argument except to say that, because it does not necessarily concern causal relations, responses could well be different from those for the causal argument. The predictions made by a "material conditional" account will depend on assumptions about how people interpret the questions; i.e., how they modify the original set of premises. To answer question i. people may suppress the statement that D is true, whilst adding the statement that B is false. If they do, the truth of D is indeterminate, because it is not entailed by the falsity of B. Alternatively, people might not suppress D. The answer would then be "yes" because the original premises state that D is true. Such an account yields a less ambiguous answer to question ii. Once people suppose that B is false, they are licensed to infer, by modus tollens, that A is false. If these "material conditional" theories make any prediction for the causal arguments, these should correspond to their prediction for comparable conditional arguments.

Experiment 1

Method. 238 University of Texas at Austin undergraduates were given one of the two arguments shown and asked the listed questions.

Results. Responses are shown in Table 1. The predictions of the causal modeling framework were supported for the causal arguments but not for the conditional arguments. The predominance of "yes" responses in the causal condition implies that for the majority of participants the supposition that B didn't occur did not influence their beliefs about whether A or D occurred. This is consistent with the idea that these participants mentally severed (undid) the causal link between A and B and thus did not draw new conclusions about A or about the effects of A from a counterfactual assumption about B. Responses to the conditional argument were more variable: no one strategy for interpreting and reasoning with conditional statements dominated.

Table 1: Percentages of participants responding "yes" to Abstract Causal and Conditional Arguments (1).

Question	Causal	Conditional
i. D holds	80%	57%
ii. A holds	79%	36%

These results were replicated with two additional arguments that used an identical causal or logical structure but added semantic content to the problems. For example,

one pair of arguments concerned a robot. Here is the causal version of that problem (Robot Causal Argument 1):

A certain robot is activated by 100 (or more) units of light energy. A 500 unit beam of light is shone through a prism which splits the beam into two parts of equal energy, Beam A and Beam B, each now travelling in a new direction. Beam A strikes a solar panel connected to the robot with some 250 units of energy, causing the robot's activation. Beam B simultaneously strikes another solar panel also connected to the robot. Beam B also contains around 250 units of light energy, enough to cause activation. Not surprisingly, the robot has been activated.

- i. If Beam B had not struck the solar panel, would the robot have been activated?
- ii. If Beam B had not struck the solar panel, would the original (500 unit) beam have been shone through the prism?

The same 238 undergraduates were given either the causal or conditional version of this problem. Their responses are shown in Table 2.

Table 2: Percentages of participants responding "yes" to Robot Causal and Conditional Arguments (1).

Question	Causal	Conditional
i. robot activated	80%	63%
ii. beam shone	71%	55%

The results are very close to those of the abstract problem except that a higher percentage of participants said "yes" in the conditional version of this problem, $z = 2.83$; $p < .01$. This may have occurred because a larger proportion interpreted the "if-then" connectives of the conditional version as causal relations. The clear physical causality of the robot problem lends itself to causal interpretation.

Experiment 2

One might argue that the difference between the causal and conditional arguments in the previous examples is not due to a greater tendency to counterfactually decouple variables from their causes in the causal over the conditional context, but instead to different pragmatic implicatures of the two contexts. In particular, perhaps the causal context presupposes the occurrence of A more than the conditional context presupposes the truth of A. It's more plausible that D would be true in the conditional arguments even if A were false than that D would have occurred in the causal arguments even if A had not. If so, then the greater likelihood of saying "yes" in the causal scenarios could be due to these different presuppositions rather than different likelihoods of undoing.

To control for this possibility as well as to replicate the effect, we examined causal and conditional versions of arguments with the following structure:

Participants were told not only that the final effect, E, had occurred, but also that the initial cause, A, had too. This should eliminate any difference in presupposition of the initial variable because its value is made explicit. To illustrate with one of the problems shown, here is the causal version of the abstract problem (Causal Argument 2):

- A causes B.
- B causes C.
- B causes D.
- C causes E.
- D causes E.
- A definitely occurred.
- E definitely occurred.

- i. If D did not occur, would E still have occurred?
- ii. If D did not occur, would B still have occurred?

The causal modeling framework predicts that a counterfactual assumption about D should disconnect it from B in the causal context so that participants should answer "yes" to both questions. Participants should only answer "yes" in the conditional context if they interpret the problem causally. Once again the predictions of a material conditional account depend on assumptions about how the questions modify the premises. A plausible assumption is that only statements mentioned in the question are suppressed. Thus in answering question ii., belief about the truth of D and B might be suspended and not-D supposed. However, this leads to a conflict because not-D implies not-B (via modus tollens) but the premises state A and thus imply B (via modus ponens). It is thus unclear whether or not they should infer B. In any case, a material conditional account must predict no difference between the causal and conditional contexts.

Method. Twenty Brown University undergraduates received either the causal or conditional versions of the abstract and robot problems described above.

Results. The results, shown in Tables 3 and 4, are comparable to those from the earlier problems, although the proportion of "yes" responses tended to be lower in the causal condition, especially for the likelihood of the beam shining if the solar panel had not been struck (only 55% in Table 4).

Table 3: Percentages of participants responding "yes" to Abstract Causal and Conditional Arguments (2).

Question	Causal	Conditional
i. E holds	70%	45%
ii. B holds	74%	50%

Table 4: Percentages of participants responding "yes" to Robot Causal and Conditional Arguments (2).

Question	Causal	Conditional
i. robot activated	90%	75%
ii. beam shone	55%	45%

A difference between causal and conditional arguments again obtained for Abstract arguments, $z = 2.20$; $p = .01$, but not for Robot ones, $z = 1.18$; n.s. The difference for Abstract arguments suggests that the earlier results cannot be attributed entirely to different pragmatic implicatures from causal and conditional contexts. The overall reduction in "yes" responses could be due to either a different participant population, some proportion of participants failing to establish an accurate causal model with these more complicated scenarios, or participants not implementing the undoing operation in the expected way (i.e., not mentally disconnecting B from D).

Failure to undo is not entirely unreasonable for these problems because D's nonoccurrence is not definitively counterfactual. The question said "If D did not occur" which does not state why D did not occur; the reason is left ambiguous. One possibility is that D did not occur because B didn't. Nothing in the problem explicitly states that the nonoccurrence of D should not be treated as diagnostic of the nonoccurrence of B.

Experiment 3

The causal modeling framework predicts that the connection between B and D should be mentally undone whenever D is explicitly prevented; when an intervention (mental or physical) outside the model determines the value of D. To simulate such a situation, we repeated Experiment 2, but made the interventional prevention of D explicit.

Method. Participants saw exactly the same sets of premises in both causal and conditional contexts, but were asked different questions, questions that made the external prevention of D explicit (Causal and Conditional Arguments 2EP). For the abstract causal context, the questions were:

- i. If somebody stepped in to prevent D from occurring, would E still have occurred?
- ii. If somebody stepped in to prevent D from occurring, would B still have occurred?

For the abstract conditional context, the questions were:

- i. If somebody stepped in and changed the value of D to false, would E still be true?
- ii. If somebody stepped in and changed the value of D to false, would B still be true?

For the robot context, the questions in the causal and conditional versions were identical (only the paragraphs describing the situation differed):

- i. If a lead barrier were placed in the path of Beam B to prevent it from striking the solar panel, would the robot have been activated?
- ii. If a lead barrier were placed in the path of Beam B to prevent it from striking the solar panel, would the original (500 unit) beam have been shone through the prism?

Responses were obtained from either 18 or 20 Brown undergraduates.

Results. Results are shown in Tables 5 and 6. The probability of saying "yes" was higher in the explicit prevention context than in its absence, but not significantly so, $z = 1.16$ and 1.39 for Abstract and Robot arguments, respectively. The two may not differ statistically because the probability of saying "yes" was already so high in the causal condition of Experiment 2. In any case, the great majority of participants acted as if explicitly preventing D caused it to have no diagnostic value for its cause (B), and that therefore other effects of the cause (E) still held. In other words, the effect of explicitly preventing D is well captured by the *do* operator.

Table 5: Percentages of participants responding "yes" to Abstract Causal and Conditional Arguments (2EP), prevention of the antecedent explicit.

Question	Causal	Conditional
i. E holds	75%	50%
ii. B holds	80%	67%

Table 6: Percentages of participants responding "yes" to Robot Causal and Conditional Arguments (2EP).

Question	Causal	Conditional
i. robot activated	75%	83%
ii. beam shone	75%	67%

An unexpected byproduct of explicit prevention was to increase the proportions of "yes" responses in even the conditional context, $z = 1.80$; $p < .05$. This probably occurred because the explicit prevention context made it more likely that the arguments would be construed causally. For example, a question beginning "If a lead barrier were placed in the path of Beam B to prevent it from striking the solar panel," may well have suggested to participants that they should construe the situation in terms of physical causation and reason about the situation using causal logic.

One implication of this observation is that the interpretation of conditionals varies with the theme of the text that the statements are embedded in. Conditionals embedded in deontic contexts are well known to be interpreted deontically (Manktelow & Over, 1990). The Abstract Conditional Arguments (1) and (2) above show that when the theme is ambiguous, the interpretation will be highly variable. Robot Conditional Argument (2EP) shows that when the theme is causal, conditionals will be interpreted causally.

Experiment 4

The final experiment attempts to replicate the observations made thus far by showing the undoing effect as well as the enhancement of the effect in an explicit prevention context. Moreover, it does so using an if-then statement in order to show that a conditional statement can be treated as causal in an appropriate context.

Method. The following scenario was described to 78 Brown undergraduates:

All rocketships have two components, A and B. Component A causes component B to operate. In other words, if A, then B.

The scenario assumes the simplest possible causal graph:

Notice that the relation between A and B is stated using an if-then construction. Approximately half the participants, in the non-explicit prevention condition, were then asked:

- i. Suppose component B were not operating, would component A still operate?
- ii. Suppose component A were not operating, would component B still operate?

The remaining half, in the explicit prevention condition, were asked:

- i. Suppose component B were prevented from operating, would component A still operate?
- ii. Suppose component A were prevented from operating, would component B still operate?

The causal modeling framework predicts the undoing effect, that participants will say "yes" to question i., Component A will continue to operate if B isn't because A should be disconnected from B by virtue of the counterfactual supposition about B. It also predicts the proportion will be higher in the explicit than non-explicit prevention conditions because the nature of the intervention causing B to be nonoperative is less ambiguous. No other framework, logical or otherwise, makes either of these predictions. Finally, the causal modeling framework predicts that people should respond "no" to the second question regardless of condition. If A is the cause of B, then B should not operate if A does not.

Results. The results are shown in Table 7. The 68% giving an affirmative answer to the first question in the Non-explicit Prevention condition replicates the undoing effect seen in the previous studies. The even greater percentage (89%, $z = 2.35$; $p < .01$) in the Explicit condition replicates the finding that the undoing effect is greater when the reason that a variable has the specified value is made explicit. Responses to the second question were almost all negative, demonstrating that people are clearly

understanding that the relevant relation is causal. This rules out an alternative explanation for the earlier studies, that people were treating causes and effects as disconnected because they didn't interpret the relations as causal but merely as correlational.

Table 7: Percentages of participants responding "yes" to questions in the Rocketship scenario given questions with antecedents non-explicitly or explicitly prevented.

Question	Non-explicit Prevention	Explicit Prevention
i. if not B, then A?	68%	89%
ii. if not A, then B?	2.6%	5.3%

Discussion

These data show that most people obey a rational rule of counterfactual inference, the undoing principle. When reasoning about the consequences of a counterfactual supposition of an event, most people do not change their beliefs about the state of the normal causes of the event. They reason as if the mentally changed event is disconnected and therefore not diagnostic of its causes. This is a rational principle of inference because an effect is indeed not diagnostic of its causes whenever the effect is not being generated by those causes but instead by mental or physical intervention from outside the normal causal system. To illustrate, when an experimenter manipulates the brightness of a computer monitor, one should not assume that the monitor needs replacing.

The demonstrations all described a deterministic causal system. The undoing principle also applies to probabilistic causes however.

These data support the psychological reality of a central tenet of Pearl's (2000) causal modeling framework. The principle is so central because it serves to distinguish causal relations from other relations, such as mere probabilistic ones. The presence of a formal operator that enforces the undoing principle, Pearl's *do* operator, makes it possible to construct representations that afford valid causal induction and inference -- induction of causal relations that support manipulation and control and inference about the effect of such manipulation, be it from actual physical intervention or merely counterfactual thought about intervention. The *do* operation is precisely what's required to distinguish representations of probability like Bayes' nets from representations of causality.

More generally, the findings are consistent in a qualitative sense with the view of cognition assumed by Pearl (2000) following Spirtes, Glymour, and Scheines (1993). Their analysis starts with the assumption that people construe the world as a set of autonomous causal mechanisms and that thought and action follow from that construal. The problems of prediction, control, and understanding can therefore be reduced to the problems of learning and inference in a network that represents causal

mechanisms veridically. Once a veridical representation of causal mechanisms has been established, learning and inference can take place by intervening on the representation rather than on the world itself. But none of this can be achieved without a suitable representation of intervention. The *do* operator is intended to allow such a representation and the studies reported herein provide some evidence that people are able to use it correctly.

Representing intervention is not always as easy as forcing a variable to some value and cutting the variable off from its causes. Indeed, most of the data reported here show some variability in people's responses. People are not generally satisfied to simply implement a *do* operation. People often want to know precisely how an intervention is taking place. A surgeon can't simply tell me that he's going to replace my hip. I want to know how, what it's going to be replaced with, etc. After all, knowing the details is the only way for me to know with any precision how to intervene on my representation, which variables to *do*, and thus what can be safely learned and inferred.

Causal reasoning is not the only mode of reasoning. But the presence of a calculus for causal inference removes any doubt that it's an important one.

Formalizing Affordance

Mark Steedman (steedman@cogsci.ed.ac.uk)

Informatics, University of Edinburgh, 2 Buccleuch Place
Edinburgh EH8 9LW, Scotland UK

Abstract

The idea that to perceive an object is to perceive its affordances—that is, the interactions of the perceiver with the world that the object supports or affords—is attractive from the point of view of theories in cognitive science that emphasize the fundamental role of *actions* in representing an agent's knowledge about the world. However, in this general form, the notion has so far lacked a formal expression. This paper offers a representation for objects in terms of their affordances using Linear Dynamic Event Calculus, a formalism for reasoning about causal relations over events. It argues that a representation of this kind, linking objects to the events which they are characteristically involved in, underlies some universal operations of natural language syntactic and semantic composition that are postulated in Combinatory Categorical Grammar (CCG). These observations imply that the language faculty is more directly related to prelinguistic cognitive apparatus used for planning action than formal theories in either domain have previously seemed to allow.

Introduction

The notion of an *affordance* (Gibson 1966) has in its most basic sense of an invariant supporting perception been extremely helpful in directing attention to non-obvious properties of the sensory array relevant to visual and haptic perception, and motor control (Lee 1980; Turvey 1990). In its more general sense of an interaction with the world that a perceived object mediates (Gibson 1979) it has proved equally attractive to a wide range of theoretical positions that have emphasized the fundamental role of the notion of *action* in human cognition (Norman 1988, 1999). This is the sense in which a door “affords” egress and ingress, a knife affords cutting and scraping, and the like. The attraction of this notion is that it seems to offer a way in which perceptual learning can be linked to the goals and actions upon the environment of the learner, an idea that has been followed up by E. Gibson and Spelke (1983), among others. However, its influence in these domains has been limited by two difficulties.

One has been the controversial idea of “direct perception”. This is the idea that the perception that a mailbox “affords letter-mailing to a letter-writing human in a community with a postal system” (Gibson 1979, p.139, citing Gibson 1950) is as directly related to properties of the sensory array as time-to-impact is to characteristics of the optic flow field for a diving gannet. It is certainly

hard to believe that the perception of such affordances is “direct” in this strong sense, although recognition of mailboxes, like that of everything else, is undoubtedly mediated *in part* by such Gibsonian invariants of the optic array as relative spatial frequency spectra, and acquisition of the mailbox artefact concept unquestionably depends upon the association of such invariants with affordances in the more general sense. I shall ignore the perceptual aspect of affordances here.

A more serious obstacle to the exploitation of the idea of affordances in this general sense has stemmed from the very fact that many such affordances are actions or events. A formal theory of events in their relation to objects that is applicable to such perceptual categorization and/or conceptual representation of artefact concepts—that is, a theory of what the affordance itself actually is, and how it actually works as a basis for effective action in the world—has been lacking.

The Linear Dynamic Event Calculus

The Linear Dynamic Event Calculus (LDEC) combines the insights of the Event Calculus of Kowalski and Sergot (1986), itself a descendant of the Situation Calculus of McCarthy and Hayes (1969) and the STRIPS planner of Fikes and Nilsson (1971), with the Dynamic and Linear Logics that were developed by Harel (1984), Girard (1987) and others.

Dynamic logics are a form of modal logic in which the \Box and \Diamond modalities are relativized to particular events. For example, if a (possibly nondeterministic) program or command α computes a function F over the integers, then we may write the following:

$$(1) \ n \geq 0 \Rightarrow [\alpha](y = F(n))$$

$$(2) \ n \geq 0 \Rightarrow \langle \alpha \rangle (y = F(n))$$

The intended meaning of the first of these is “in any situation in which $n \geq 0$, after every execution of α that terminates, $y = F(n)$ ”. That of the second is (dually) that “in any situation in which $n \geq 0$, there is an execution of α that terminates with $y = F(n)$ ”.

We can think of these modalities as defining a logic whose models are Kripke diagrams in which accessibility between possible worlds is represented by events. Such events can be defined as mappings between situations or partially specified possible worlds, defined in

terms of conditions on the antecedent which must hold for them to apply (such as that $n \geq 0$ in (1)), and consequences (such as that $y = F(n)$) that hold in the consequent.

The particular dynamic logic that we are dealing with here is one that includes the following dynamic axiom, which says that the operator $;$ is *sequence*, an operation related to *functional composition* over events, viewed as functions from situations to situations:

$$(3) [\alpha][\beta]P \Rightarrow [\alpha;\beta]P$$

Using this notation, we can conveniently represent, say, a plan for *getting outside* as the composition of *pushing* a door and then *going through* it, written *push';go-through'*.

Composition is one of the most primitive *combinators*, or operations combining functions, which Curry and Feys (1958) call **B**. It can be defined by the following equivalence with a lambda term:

$$(4) B\alpha\beta \equiv \lambda s.\alpha(\beta s)$$

Plans like *push';go-through'* could be written in Curry's notation as $Bpush'go-through'$

Situation/Event Calculi and the Frame Problem

The situation calculi are heir to a problem known in the AI literature as the Frame Problem (McCarthy and Hayes 1969). This problem arises because the way that we structure our knowledge of change in the world is in terms of event-types that can be characterized (mostly) as affecting just a few fluents among a very large collection representing the state of the world. (Fluents are facts or propositions that are subject to change). Naive event representations which map entire situations to entire other situations are therefore representationally redundant and inferentially inefficient. A good representation of affordances must get around this problem.

To avoid the frame problem in both its representational and inferential aspects, we need a new form of logical implication, distinct from the standard or intuitionistic \Rightarrow we have used up till now. We will follow Bibel et al. (1989) and others in using *linear* logical implication \multimap rather than intuitionistic implication \Rightarrow in those rules that change the value of fluents.

For example, we can represent events involving doors in a world (simplified for purposes of exposition) in which there are two places *out* and *in* separated by a door which may be *open* or *shut*, as follows:

$$(5) \begin{array}{ll} \text{a. } shut(x) \multimap [push(y,x)]open(x) \\ \text{b. } open(x) \multimap [push(y,x)]shut(x) \end{array}$$

¹We follow a logic programming convention that all variables appearing in the consequent are implicitly universally quantified and all other variables are implicitly existentially quantified. Since in the real world doors don't always open when you push them, box must be read as *default* necessity, meaning "usually".

$$(6) \begin{array}{ll} \text{a. } in(y) \multimap [go-through(y,x)]out(y) \\ \text{b. } out(y) \multimap [go-through(y,x)]in(y) \end{array}$$

Linear implication has the effect of building into the representation the update effects of actions—that once you apply the rule, the proposition in question is "used up", and cannot take part in any further proofs, while a new fact is added. The formulae therefore say that if something is shut and you push it, it becomes open (and vice versa), and that if you are in and you go through something then you become out (and vice versa).

To interpret linear implication as it is used here in terms of proof theory and proof search, we need to think of possible worlds as states of a single updatable STRIPS database of facts. Rules like (5) and (6) can then be interpreted as (partial) functions over the states in the model that map states to other states by removing facts and adding other facts. Linear implication and the dynamic box operator are here essentially used as a single state-changing operator: you can't have one without the other.

The effect of such systems can be exemplified as follows. If the initial situation is that you are in and the door is shut:

$$(7) in(you) \wedge door(d) \wedge shut(d)$$

—then the linear rules (5) mean that an attempt to prove the proposition in (8) concerning the state of the door in the situation that results from pushing the door will fail because rule (5a) has removed the fact in question from the database that results from the action *push(you,d)*:²

$$(8) [push(you,d)]shut(d)$$

On the other hand, attempts to prove the following will all succeed, since they are all facts in the database that results from the action *push(you,d)* in the initial situation (7):

$$(9) \begin{array}{ll} \text{a. } [push(you,d)]open(d) \\ \text{b. } [push(you,d)]door(d) \\ \text{c. } [push(you,d)]in(you) \end{array}$$

The advantage of interpreting linear implication in this way is that it builds the STRIPS treatment of the frame problem (Fikes and Nilsson 1971) into the proof theory, and entirely avoids the need for inferentially cumbersome reified frame axioms of the kind proposed by Kowalski (1979) and many others (see Shanahan 1997).

Using linear implication (or the equivalent rewriting logic devices or state update axioms of Thielscher (1999) and Martí-Oliet and Meseguer (1999)) for STRIPS-like rules makes such frame axioms unnecessary. Instead, they are theorems concerning the linear logic representation.

Even in this extremely simplified world, we need a little more apparatus to represent our knowledge about doors in a way which will allow us to make plans in-

²We follow the logic programming convention of negation by failure, according to which a proposition is treated as false if it cannot be positively proved to be true.

volving them. We also need to state preconditions on the actions of pushing and going through. Here ordinary non-linear intuitionistic implication is appropriate:³

- (10) a. $door(x) \wedge open(x)$
 $\Rightarrow possible(go-through(y, x))$
 b. $door(x) \Rightarrow possible(push(y, x))$

These rules say (oversimplifying wildly) that if a thing is a door and is open then it's possible to go through it, and that if a thing is a door then it's possible to push it.

We also need to define the transitive property of the possibility relation, as follows, using the definition (3) of event sequence composition:

- (11) $possible(\alpha) \wedge [\alpha]possible(\beta) \Rightarrow possible(\alpha; \beta)$

This says that any situation in which it is possible to α , and in which actually doing α gets you to a situation where it is possible to β , is a situation in which it is possible to α then β .

If we regard actions as functions from situations to situations, then this rule defines *function composition* as the basic plan-building operator of the system. Composition is one of the simplest of a small collection of combinators which Curry and Feys (1958) used to define the foundations of the λ -calculus and other applicative systems in which new concepts can be defined in terms of old. Since the knowledge representation that underlies human cognition and human language could hardly be anything *other* than an applicative system of some kind, we should not be surprised to see it turn up as one of the basic operations of planning systems.

This fragment gives us a simple planner in which starting from the world (12) in which you are *in*, and the door is *shut* and stating the goal (13) meaning "find a possible series of actions that will get you *out*," can, given a suitable search control, be made to automatically deliver a constructive proof that one such plan is (14), the composition of *pushing*, and *going through*, the door:

- (12) $in(you) \wedge door(d) \wedge shut(d)$

- (13) $possible(\alpha) \wedge [\alpha]out(you)$

- (14) $\alpha = push(you, d); go-through(you, d).$

One way to produce this proof, which is suggested as an exercise, is via *backward-chaining* from the goal (13) on the consequents of rules (10) using the transitivity rule (11). The situation that results from executing this plan in the start situation (7) is one in which the following conjunction of facts is directly represented by the database:

- (15) $out(you) \wedge door(d) \wedge open(d)$

This calculus is developed further in Steedman 1997, 2002 in application to more ambitious plans, such as the "monkey and bananas" problem, and a number of gener-

alizations of the frame problem, using on a novel analysis of *durative* events extending over intervals of time, which are ignored here.

However, we have said nothing yet about the problem of *search* implicit in searching for and identifying such plans.

Formalizing Affordance using LDEC

Although the example is simplified for purposes of exposition (in particular, with respect to the problem of *durativity*), it provides the basis for a quite general calculus of events. (See Shanahan (1997), Thielscher 1999, and Steedman (1997, 2000b) for related proposals including discussions of ramification, qualification, delayed action, simultaneity, nondeterminism and other standard problems that such representations have to deal with.)

In fact the representation of actions and events in terms of an association of preconditions and consequences with the core event is a very generally applicable one. If the precondition is a conditional stimulus such as a light, and the consequence is a reward, such as food, while the action concerned is pecking or pressing a bar, then it can be considered as a representation of an *operant* in the cognitive sense of Rescorla and Wagner (1972), itself a notion closely related to that of an *affordance*.

It also provides the basis for a formalization of the relation between objects and their affordances, of the kind that we need in order to talk about perceptual and cognitive learning in non-linguistic animals and prelinguistic children. For example, the facts in (5) and (6) strike me as a pretty good representation of what my cat knows about the affordances of doors. Of course, the representation is perfectly neutral concerning the invariants that afford the perception of doors in the first place, their relation to bodily properties like the size of the cat's head, and aspects relevant to learning such as motor embedding of the actions of pushing and going through, and so on. It is a representation of what sort of thing it is that is perceived and learned. Nevertheless, the representation could be used to explain the transition she made in her perceptual learning from a stage where doors afforded her (6) (going through for purposes of egress and ingress) but not (5) (pushing to open and close), homing in via a set of superstitious and rapidly extinguishing spurious affordances to a correct affordance (5) supporting the motor plan (14) and its internalization as yet another affordance of doors. The representation also suggests a basis for experimentally investigating precise details of the cat's representation of the affordances of doors. (For example, do they afford her the ingress and egress of other cats?) Many of these experiments have already been done—most notably, by Köhler (1925), in his investigations of tool use and planning in Chimpanzees.

One of Köhler's most thought-provoking observations concerning such planning was the following. A chimpanzee which was perfectly capable of consistently using a tool such as a stick to reach otherwise unattainable objects—one to whom sticks afforded reaching—was unable to enact such a plan unless the stick was ac-

³The version of linear logic mixing linear and standard implication is closely related to "Bunched Implication Logic" (see Pym 2001, which gives an extensive treatment of its semantics and proof theory, including a cut elimination theorem).

tually present in the problem situation. Mere availability of a stick in an adjoining room—even one which the ape had recently explored—was not enough to trigger the relevant knowledge and cause the ape to fetch the stick.

This observation suggests that for non-linguistic animals, including those closest to us in evolutionary terms, access to the affordances of objects is tied to immediate perception of the objects themselves, as Gibson believed. For an animal, this is quite a good way of running your planner. If you don't have much control over your physical environment, it is probably better to look at those plans the situation affords, rather than backward chaining to conditions that there may be no way for you to satisfy, say because of the time of year. This in turn suggests, uncontroversially, that affordances like egress are indexed in such animals by object-concepts like *door*, rather than by end-states like being *out*, and that planning proceeds *reactively* by forward chaining from what is the case, rather than backward chaining from the goal.

We can represent such indexing by first defining actions like *pushing* and *going through* as functions like the following derived from (5) and (6):

$$(16) \text{ a. } \textit{push}(y,x) \rightsquigarrow \left\{ \begin{array}{l} \textit{shut}(x) \multimap \textit{open}(x) \\ \textit{open}(x) \multimap \textit{shut}(x) \end{array} \right\}$$

$$\text{ b. } \textit{go-through}(y,x) \rightsquigarrow \left\{ \begin{array}{l} \textit{in}(y) \multimap \textit{out}(y) \\ \textit{out}(y) \multimap \textit{in}(y) \end{array} \right\}$$

(Here \rightsquigarrow reads as “yields”. The linear implication symbol \multimap is overloaded to signify linear mapping of state to state accompanied by deletion and addition of facts. Implication is so closely related to functional mapping, and the functions in question are so closely related to the state update or rewrite axioms of the proof theory that this overloading seems unlikely to cause confusion.)

The set of such functions *Affordances*(*door*) constitutes the affordances of doors:

$$(17) \textit{Affordances}(\textit{door}) = \left\{ \begin{array}{l} \textit{push} \\ \textit{go-through} \end{array} \right\}$$

The Gibsonian affordance-based door-schema *door'* can then in turn be defined as a function mapping doors into (second-order) functions from their affordances like pushing and going-through to their results:

$$(18) \textit{door}' = \lambda x_{\textit{door}}. \lambda p_{\textit{Affordances}(\textit{door})}. px$$

The operation of turning an object of a given type into a function over those functions that apply to objects of that type is another primitive combinator called **T** or *type raising*. As in the case of composition (4), the effect of this combinator can be defined by equivalence to the corresponding λ -term:

$$(19) \textbf{T}x \equiv \lambda p. px$$

Accordingly, (18) can be rewritten:

$$(20) \textit{door}' = \lambda x_{\textit{door}}. \textbf{T}x$$

Such a concept of doors is useful for reactive planning, and one can add more affordances to *Affordances*(*door*) as one's experience increases. It seems quite likely that

this is close to the way cats or at least chimpanzees conceptualize doors.

However, in human terms it is a somewhat stultifying representation, in that it restricts the concept to previously encountered events involving doors that one has somehow stumbled across. One would like to have the advantages in terms of efficiency of planning that thinking of objects in terms of their affordances allows, while also being able envisage novel uses for doors—for example, using one as a table, or as a raft—when circumstances demand it. In other words, one would like to be able to generalize (18) over a wider range of affordances, such as the affordances of natural kinds such as flat movable objects, or of other things that you can push and/or go through. However, there are reasons to think our ability to generalize very far beyond natural kinds and directly experienced affordances is quite limited. (For example, people find considerable difficulty in solving those irritating conundrums which require one to see that a pair of pliers affords the weight for a plumbline, or that the box that thumbtacks are packaged in affords a bracket that can be thumbtacked to the wall to provide a support for a candle.) It seems likely that the basis for such limited generalization is partly perceptual, and partly embedded in our modes of interaction with objects, as Gibson insisted.

Combinatory systems that include both composition and type raising are quite expressive—see Smullyan (1985, 1994) for discussion. They have the character of calculi for rebracketing and permuting terms in expressions. Such calculi are closely related to linear logic itself—see Lambek (1988) for discussion. In this connection it is interesting that the theory of Combinatory Categorical Grammar (CCG, Ades and Steedman 1982, Steedman 2000a) implies that the grammar of all languages involves both type-raising of argument categories and composition of predicates.

Combinatory Grammars

CCG, like other varieties of Categorical Grammar, is a theory in which all linguistic elements are categorized or typed as either functions or basic types, and in which syntactic derivation is achieved by syntactic rules corresponding to directionally and categorially restricted versions of a small number of combinators prominently including composition **B** and **T**. Thus it is a theory that makes language look as if it has been built on a pre-existing system for planning action in the world, and thereby seem less unique as a cognitive faculty than is usually assumed.

While readers must be directed elsewhere for a full presentation, it may suffice for present purposes to merely note that in CCG elements like verbs are associated with a syntactic “category” which identifies them as *functions*, and specifies the type and directionality of their arguments and the type of their result. For example, a ditransitive verb (DTV) is a function from (indirect object) NPs on the right into transitive verbs (TV)—that is, into functions from (direct object) NPs on the right into

VP:⁴

(21) $\text{give} := (VP/NP)/NP$

Such a DTV is a (curried) function that can apply to its arguments to yield VP, as follows:

(22)
$$\frac{\frac{\text{give} \quad \text{Bill a biscuit}}{(VP/NP)/NP \quad NP} \rightarrow VP/NP}{VP} \rightarrow$$

However, the involvement of further combinatory operations engenders a wide variety of coordination phenomena characteristic of all languages of the world, including English “argument-cluster coordination”, “backward gapping” and verb-raising constructions in Germanic languages, and English gapping. The first of these is illustrated by the following analysis, from Dowty (1988):

(23)
$$\frac{\frac{\text{give} \quad \text{Bill a biscuit} \quad \text{and} \quad \text{Harry an apple}}{DTV \quad TV \backslash DTV \quad VP \backslash TV \quad CONJ \quad TV \backslash DTV \quad VP \backslash TV} \xrightarrow{VP \backslash DTV} VP \backslash DTV}{VP} \xrightarrow{VP \backslash DTV} \langle \Phi \rangle$$

The type-raising and composition rules, indicated by T and B respectively, guarantee that the semantics of non standard constituents like *Bill a biscuit* is such as to reduce appropriately with a ditransitive verb like *give*. It is in fact a prediction of the theory that such a construction can exist in English, and its inclusion in the grammar requires no additional mechanism whatsoever.

The earlier papers show that no *other* non-constituent coordinations of dative-accusative NP sequences are allowed in any language with the English verb categories, given the assumptions of CCG. Thus the following are ruled out in principle, rather than by stipulation:

- (24) a. *Bill to Sue and introduce Harry to George
b. *Introduce to Sue Bill and to George Harry

Examples like (23) have often been described in terms of very powerful mechanisms of “deletion under identity” of missing elements like the verb *give* in the right conjunct. However, unlike CCG, such proposals fail to explain the observation that such deletions preserve word order, in the sense that in both coordinate and canonical sentences of English, *verbs are to the left of their complements*.

This observation is merely the English specific manifestation of a generalization concerning Universal grammar, due to Ross (1970), who noted that when verbs are “deleted” in this way in languages with other “basic” word orders, such as verb-final (SOV) and verb initial

(VSO) languages, they always do so in a way that preserves the canonical left-to-right ordering of verb and argument, thus:⁵

- (25) VSO: *SO and VSO VSO and SO
SOV: SO and SOV *SOV and SO

Logical and Neurological Relations between Language and Action

The ubiquitous appearance of composition B and type-raising T in both affordance-mediated action planning of the most elementary sort on the one hand, and universal grammar on the other, strongly suggests that the language faculty in its syntactic aspect is directly hung onto a more primitive set of prelinguistic operations including these combinators, originally developed for motor planning. This hypothesis has strong implications for the theory of evolution and the child’s acquisition of language, for which there is considerable circumstantial evidence from neurological and neuroanatomical observations.

The Linear-Dynamic Event Calculus and related linear and STRIPS-like systems offer a way of representing actions in ways that are useful for planning action. This in turn offers a way of capturing affordances of objects, a notion that is relevant to doing so efficiently, and which is therefore relevant to perceptual categorization and concept learning relevant to tool-use. Two combinatory operations of composition and type-raising play a central role in this process. Those same combinators appear in syntactic guise in natural language, where they provide the basis for an explanatory account of language-specific constructions and cross-linguistic universal generalization, and where a considerable body of evidence from neuroanatomy and child development that has been adduced in support of the Motor Theory suggests that planning and language are closely related. LDEC and CCG make that relation look direct enough to explain the fact that the evolutionary advance in question appears to have been very rapid indeed.

It is interesting to speculate upon what such an evolutionary step might be based. One strong candidate is the attainment of the modal and propositional attitude concepts that are necessary to support a theory of other minds—that is, functions over propositional entities. (We have so far glossed over an important distinction between plans, which compose actions of type *state* \rightarrow *state*, and grammar, which composes functions of type *proposition* \rightarrow *proposition* or *property* \rightarrow *property*.)

It is propositional functions that induce true recursion in both conceptual structures and grammar. There is no evidence that apes entertain such concepts. In particular, the most successful attempts to teach apes to use language, notably those involving ASL and other manipulative languages, show a lack of recursive syntax coupled

⁴We here use the “result leftmost” notation in which a rightward-combining functor over a domain β into a range α are written α/β , while the corresponding leftward-combining functor is written $\beta \backslash \alpha$. (α and β may themselves be function categories.) There is an alternative “result on top” notation, according to which the latter category is written $\beta \backslash \alpha$.

⁵Interestingly, SVO languages like English pattern with verb initial languages in this respect, rather than with verb final. This fact and certain apparent exceptions to Ross’s generalization arising in languages with more than one “basic” word order are discussed in Steedman 2000a.

with an almost autistic paucity of conversational initiative. Perhaps it is *only* the lack a theory of mind and the associated propositional attitude concepts that holds apes back from developing human language on the basis of their planning abilities, a suggestion consistent with the views of Tomasello 1999.

Providing Distinctive Cues to Augment Human Memory

Abstract

Previous research in our lab (Tan, Stefanucci, Proffitt & Pausch, 2001) demonstrated that a multimodal prototype computer system, the InfoCockpit, could increase users' memory of information compared to a standard desktop computer. Displaying information on multiple monitors with ambient visual and auditory displays engages context-dependent memory and memory for location, thus facilitating recall. We replicate this finding and isolate the memory cues to find whether the combination of contextual information and spatial location is necessary to obtain this memory advantage. Our findings show that contextual information alone provides users with the best strategy for later recall.

Introduction

In the past years, computer interfaces have been designed with the goal of promoting usability. These interfaces have a consistent "look and feel" that fosters usability but does not help the user remember information learned on the system. Our research examines a newly built interface, termed the InfoCockpit, which supports and aids human memory and performance while preserving usability.

The design of the InfoCockpit is based on psychological research that has uncovered many ways of improving memory through the use of spatial and environmental memory cues. These cues are incorporated into the InfoCockpit so that users can more easily recall information that they learn on the computer. This system provides users with "locations" and "places" to hook their memories onto without compromising usability.

Creating Place

Memories are tied to the environmental context in which they take place (Smith, Glenberg, & Bjork, 1978). For example, one might try to help a friend remember a conversation by referencing the context of that conversation (e.g. "don't you remember we talked about this at the coffee shop downtown?"). Having recalled the place of the conversation, the friend can more easily remember what was said. This strategy

recruits an important cue for human memory; the context or "place" is a reference to start a search for the information discussed. Being in places, or referencing them, evokes memories and increases the chances of remembering information.

Psychologists have researched the use of environmental context as a cue for memory for the past few decades (Godden & Baddeley, 1975; Smith, Glenberg & Bjork, 1978). Smith (1979) found that people associate information and the environmental context in which it is learned. Although these associations are often incidental, they can be useful retrieval cues when recalling information. Smith (1982) also had participants encode information in multiple learning environments or different "places". He showed that the amount of information recalled increases when learning takes place in different contexts. In further studies, however, Smith (1984) found that recall performance in multiple learning contexts was not significantly improved when participants returned to the place that they were in at the time of encoding. Diverse learning environments provide a memory advantage over a single learning environment but this advantage is not contingent upon reinstatement of the context at retrieval.

In addition to the number of learning environments, contexts that are distinctive can also increase memory performance. Places that draw attention are the most effective in producing a memory advantage (Smith, Vela, & Williamson, 1988). Learning information through different sensory modalities can create a distinctive context. In addition to visual cues, ambient three-dimensional sounds can serve as distinctive cues for memory. It has been shown that ambient sounds enhance memory for visual information presented in their context (Davis, Scott, Pair, Hodges, & Oliverio, J., 1999).

Providing Location

Memories are also tied to a location in space (Gordon, 1903). Whereas we use "place" to denote an ambient environmental context, "location" refers to the position of information within that "place". We cannot help but

notice, for example, the position of an object in a room. The location of that object in space is processed preattentively and remembered almost automatically (Logan, 1998). Similarly, most people comment that they can remember where on a page they read something without remembering the information they read. Several studies confirmed this anecdote by showing the reliability of spatial location as an important memory cue (Rothkopf, 1971; Zechmeister & McKillip, 1972). Given the evidence above, it follows that spatially distributed information is easier to remember than information presented in a single location (Gordon, 1903).

Combining Location and Place: The InfoCockpit

The InfoCockpit (see Figure 1) uses multiple projectors to display a panoramic image of a "place" onto large screens. It provides a context for users to reference when they are retrieving information from memory. Ambient three-dimensional surround sound is added to immerse the user in the place. For example, panoramas of a woodland scene are projected with consistent 3D sounds like leaves rustling, birds chirping, and insects. The InfoCockpit provides spatial cues by presenting information to users on multiple monitors. When learning the information, users inadvertently notice on which monitor information is presented. We hypothesized that users would be more likely to remember the information if they could recall on which monitor it was presented.

Figure 1. – The InfoCockpit uses multiple monitors to provide "location" cues and ambient visuals with three-dimensional sounds to create "place" cues.

This system stands in stark contrast to current desktop systems, which present all information to the user on a single monitor, and do not display a place cue. Desktop users do not have to orient themselves to information; windows simply bring information to them. There are no spatial cues encoded with the information and no way of easily retrieving information by remembering the context in which it was seen.

Previous research has not attempted to construct environments that present "location" and "place" cues to systematically examine whether a large effect can be obtained. In our lab, we combined these cues (location and place) to see if they produced a greater memory advantage than when presented independently (Tan, Stefanucci, Proffitt, Pausch, 2001). Tan et al. found that users of the InfoCockpit had a 56% improvement in memory performance when compared to users of a standard desktop computer.

The current paper addressed whether users of the InfoCockpit systematically relied on one cue over the other or if the combination of "location" and "place" was the best way to promote later recall. Each of the cues was examined in isolation to assess its solitary contribution to the larger effect. Based on our previous findings, we assumed that participants using the InfoCockpit would be able to remember more than participants using a standard desktop computer. And indeed, this was true. In addition, we hypothesized that "more is better"; participants in the InfoCockpit condition would remember significantly more word pairs than participants who received "location" or "place" cues in isolation. Contrary to our hypothesis, our experiment revealed that participants receiving only "place" cues performed significantly better than participants in all other conditions.

Method

Participants

Eighty University of Virginia students (40M, 40F) participated in the experiment. Participants were paid \$20 for their participation. They were naïve to the purposes of the experiment and had not participated in a previous memory experiment like this one.

Apparatus

The apparatus used to display materials, the InfoCockpit, is a large multiple screen display system (see Figure 1). The displays are run from a Dell Precision Workstation with 620 Pentium III Xeon dual processors. Installed in the Dell are two Appian Jeronimo Pro 4-port graphics cards that allow the computer to drive the six display screens. Two sets of displays are arrayed three across, with NEC 18" LCD monitors directly below the projection surfaces. The LCD monitors serve as the main working area on which users interact with information. The projection displays provide a horizontal viewing angle of approximately 145 degrees and are used to immerse the user in a particular place. Three Sharp Notevision 6 projectors (2200 lumens) display the context images on the projection screens.

We created and played back audio contexts on a Macintosh G4 using a Digidesign Pro Tools Mix24

digital audio workstation. The contextual environments were comprised of 6 channels of sound. Speakers were placed surrounding the user at ear level and at 4 feet above ear level, +/- 30 degrees at ear level, and +/- 120 degrees at 4 feet above ear level. The ear level speakers were 5 feet away from the user while the speakers above were 8 feet away.

Procedure

The experimental design consisted of two phases: a training phase and a testing phase.

Training Phase Participants learned three lists of words, each list containing ten pairs of words (all common, high frequency nouns). All participants learned the lists one at a time. Each list consisted of 10 cue words and 10 target words. The 10 cue words were the same for the 3 lists, but the target words varied from list to list (i.e. 'plate-passenger', 'plate-string', and 'plate-scientist'). We named the lists Lawn, Museum, and History to help the participants parse the lists in memory. For the participants in the InfoCockpit or Context conditions, these names referred to projected places.

The training phase consisted of both a study period and a learning period. During the study period participants were presented with each pair of words once (for 5 seconds each). After study was completed, the learning task began. One of the cue words from a pair was randomly presented to the participants. Participants then typed the target word that went with the cue. Feedback was given to the participants. If they were incorrect, the correct word was presented. Another cue word would then appear and they would have to type its target. This went on iteratively until participants had recalled all of the pairs correctly in one iteration (meeting 100% criteria). This ensured that all participants' knowledge of the material was equivalent before testing. Participants had unlimited time to finish the learning portion. The procedure for learning the word lists was explained to participants before training began.

Participants were assigned to one of four conditions (Desktop, InfoCockpit, Spatial, or Context) defined by the display configuration on which they learned pairs of words. An equal number of males and females were randomly assigned to each condition. Participants in the InfoCockpit group studied and learned the word lists, each on a different monitor and associated with different contextual images and sounds. For example, participants would see images and hear sounds from a museum while they were learning the word pairs for the "Museum" list on the middle monitor.

The Desktop group performed the task on a standard desktop computer with a single monitor. They learned the same three lists (Lawn, Museum, and History) on one screen, with no projected context images or three-dimensional sounds.

For the Spatial condition, participants learned the three word lists on different monitors. However, they did not learn the lists in different projected contexts. They also had no sounds. This condition was designed to assess the individual contribution of spatial cues in the InfoCockpit.

Participants in the Context condition learned the three lists on one monitor. Each list was presented with its corresponding context. Participants learned the lists with the projected context images and sounds, all on the same monitor. This condition tested the importance of contextual place cues on learning in the InfoCockpit.

Testing Phase The testing phase of the experiment took place a day later. All participants returned to the lab and were tested on how many word pairs they remembered from the training phase. Retrieval was done on a laptop in a different room than the training phase. Participants were given cue words from each of three lists, one list at a time, and were asked to type in as many of the targets as they could remember. They received no feedback on their performance.

Results

Out of 30 possible items, the mean recall scores were 8.80 for the Desktop group, 11.65 for the InfoCockpit group, 9.60 for the Spatial group, and 15.05 for the Context group. A one-way analysis of variance (ANOVA) comparing the four conditions revealed significant differences between the groups, $F(3, 76) = 9.065$, $p < 0.000$ (see Figure 2). Post hoc comparisons using the Fisher LSD test showed that participants in the Context condition recalled significantly more word pairs than the Spatial, Desktop and InfoCockpit conditions. In addition, the InfoCockpit condition remembered significantly more word pairs than the Desktop condition. A one-way analysis of variance (ANOVA) comparing number of iterations to learn the word pairs to criteria did not show a significant difference among the conditions, $p = 0.762$.

Figure 2. Number of word pairs recalled by each condition.

Discussion

InfoCockpit participants remembered significantly more word pairs than participants using a standard desktop computer. Adding "location" and "place" cues to a computer enhanced participants' memory for information learned on that system. This conclusion replicates previous research from our lab (Tan, Stefanucci, Proffitt, Pausch, 2001).

We assumed the individual components of the InfoCockpit would improve memory with relation to the standard desktop computer, but we did not believe they would be as effective as the ensemble of cues. Our hypothesis that "more is better" was incorrect for this task. Participants receiving only "place" cues at encoding recalled more words than participants in all other conditions.

This finding may be a consequence of the strategy the InfoCockpit participants used when retrieving the word pairs. We believe these participants had two strategies available at recall for remembering the information. One of the strategies involved the location of the list on one of the monitors. Participants could retrieve the appropriate target by recalling the location of the monitor on which it was learned. Likewise, InfoCockpit participants could access environmental place cues to recall the pairs. To remember the target word they could imagine the contextual images and sounds displayed when learning the pair. It is possible that these two recall strategies interfered with each other, compromising the best recall strategy (simply recalling the "place" cue) by the evoking the less effective location recall strategy. In the task we describe, the contextual place information was a more reliable cue for later recall and those participants in the Context condition were able to exploit it to the fullest.

While participants in the InfoCockpit condition performed better than participants in the standard desktop computer, they were not as successful as participants in the Context condition. Providing users with a single cue in isolation (place) was more effective than providing them with two sets of cues. This finding

is not surprising given previous research. For instance, Jones (1976) and Smith (1984) found that isolated cues could help their participants retrieve an entire memory, even when combinations of cues were present at encoding. More recently, Parker and Gellatly (1997) showed that an increase in the amount of cues at encoding did not produce a reliable increase in recall. They gave their participants both music and odors while encoding information. At retrieval, either both or only one of the cues was reinstated. In either condition, participants recalled the same amount of information. In contrast, our findings suggest that participants receiving only one of the cues (place) at encoding had an advantage over the other conditions. The type of cue we used may account for the difference. Perhaps the place cue was more distinctive than the location cue and people were more successful in associating it with the words. The "more is better" approach to the design of computer interfaces should be examined closely because there may be situations in which a "less is more" attitude can augment performance to a higher degree.

Conclusions

The InfoCockpit increased memory compared to a standard desktop computer. It utilized both "place" and "location" cues to facilitate memory retrieval. When presented with "place" cues in isolation, participants' memory performance increased significantly in comparison to performance on the InfoCockpit. Providing multiple memory cues at encoding increases recall. However, interference between contextual and spatial cues may have a negative effect on performance. Evaluation of the interactions between cues, as well as the cues themselves, is necessary to ensure a complete understanding of the role that these cues play in memory.

Acknowledgments For their collaboration on this project, we would like to thank Tom Banton, Cedar Riener, and Jessi Witt of the Proffitt Perception Lab at the University of Virginia; Barbara Spellman at the University of Virginia; Adam Fass, Andrew Faulring, Desney Tan and Randy Pausch of the Stage 3 Research Lab at Carnegie Mellon University; Chris Kyriakakis at the University of Southern California. Many thanks to Shawn O'Hargan and Jae Lee for their help in collecting the data.

Abstract

The mental model theory postulates that reasoners build mental models of the situations described in premises, and that each model represents a possibility. The theory's main principle — the principle of *truth* — is that these representations are incomplete, because mental models represent only what is true, and not what is false. The present paper defends an analogous principle of *self-interest*: when individuals have to think strategically, they tend to represent only their own options and payoffs, not those of their opponents. Four experiments have corroborated this principle.

Introduction

Strategic thinking underlies those decisions that depend on what other individuals are likely to decide. Such decisions are ubiquitous in business, politics, and daily life. To outwit an adversary, or to maximize the benefits of co-operation with a partner, you often need to think about what this other individual is likely to choose to do. The theory of games provides a normative theory of strategic thinking, especially since John Nash's theorem determining those strategies that are optimal for all players — the so-called Nash equilibrium (see, e.g., Dixit and Nalebuff, 1991). However, as Reinhard Selten, co-winner of the Nobel prize with Nash in 1994, has remarked: game theory is rational theology (personal communication). That is, naive individuals in daily life are unlikely to abide by its canons of rationality. The term *naive* here refers to individuals who have not mastered game theory; it does not impugn their intelligence. Thinking about what other people may be thinking is indeed likely to be difficult, because it calls for a representation, not only of your own state of mind, but also of another person's preferences, and for inferences about

their likely strategies. If you fail to think through their optimal strategy, then you are unlikely to select a rational strategy for your self.

Consider as an example a simple game in which you have two options (A and B), your opponent has two options (A and B), you both make your choices simultaneously, and you both receive payoffs as a function of your choices. We show your payoff followed by your opponent's payoff in each cell:

		Your opponent's options	
		A	B
Your options	A	\$4/\$4	\$1/\$3
	B	\$2/\$4	\$6/\$1

If your opponent chooses A then you should choose A and receive \$4. But, if your opponent chooses B, you should choose B and receive \$6. Hence, to make the right choice you should think about what your partner is likely to choose. If she is rational, she should think: If I choose A, then regardless of what my opponent chooses, I get \$4; but if I choose B, then regardless of what my opponent chooses, I will get less than \$4. Therefore, I should choose A (because B is *dominated* by this strategy). Hence, if you are rational and you know that your opponent is rational, then you should choose A. This sort of thinking exemplifies game theory, which formalizes optimal strategies on the assumption that players are rational.

In contrast, the present paper argues that the task of inferring rational predictions about other players' choices is too difficult for naive human players. The paper accordingly proposes an alternative account of how naive individuals make strategic decisions.

Mental Models and Naive Strategic Thinking

The mental model theory postulates that

reasoning depends on understanding the meaning of premises and using this meaning and general knowledge to envisage the states of affairs that are possible given the truth of the premises (Johnson-Laird and Byrne, 1991). Each mental model represents a possibility. A conclusion is necessary if it holds in all the models of premises. It is possible if it holds in at least one model of premises (Bell and Johnson-Laird, 1998). And its probability — its likelihood of being true — depends on the proportion of models of the premises in which it is true (Johnson-Laird, Legrenzi, Girotto, Legrenzi, and Caverni, 1999). The theory has also been extended to account for meaning and reasoning with causal relations (Goldvarg and Johnson-Laird, 2001). A fundamental assumption of the theory is the principle of *truth*: in order to minimize the load on working memory, mental models normally represent only what is true. The failure to represent what is false gives rise to illusory inferences of various sorts, i.e. inferences that nearly everyone makes, but that are wrong (see, e.g., Goldvarg and Johnson-Laird, 2000).

The model theory extends naturally to human strategic thinking. It postulates that individuals construct mental models of the options and payoffs. In order to minimize the load on working memory, however, the theory is based on an assumption analogous to the principle of truth. According to the principle of *self-interest*, mental models normally represent only individuals' own options and payoffs. The failure to represent other players' payoffs should give rise to systematic errors in strategic thinking. The aim of our experiments was to test the principle of self-interest.

Experiment 1: Games as payoff matrices

Our first experiment examined whether or not individuals spontaneously represent their partner's payoffs in games in which their optimal choice depends on their partner's choice. The participants played 25 games, each presented in the form of a payoff matrix. Five of the games were *independent*, that is, the participants' optimal choice did not depend on their partner's choice. Here is an example of an independent game in which only the participant's payoffs are shown:

		Your partner's options	
		A	B
Your options	A	\$5	\$6
	B	\$4	\$5

In the absence of information about their partner's payoffs, there are three possible strategies that the participants could adopt:

- 1) They could maximize their mean payoffs. In this game it is option A, which leads to a mean payoff of \$5.5.
- 2) They could maximize their minimum gain. Option A yields the larger minimum gain (of \$5).
- 3) They could maximize their maximum gain. Option A yields the maximum gain (of \$6). Hence, in general, with independent games all three strategies lead to the same choice.

The remaining 20 games were *dependent*, that is, to make the optimal choice, the participants needed to know their partner's choice, e.g.:

		Your partner's options	
		A	B
Your options	A	\$5	\$7
	B	\$6	\$4

Here, if the partner chooses A, then the participant should choose B, whereas if the partner chooses B, the participant should choose A. Granted the principle of self-interest, however, the participants should not notice the difference between independent and dependent games. They should be prepared to play both sorts of game without knowledge of their partner's payoffs. In the present game, the three preceding strategies all lead to the choice of option A. The experiment included three other sorts of dependent game that allowed us to identify the participants' strategies.

We tested 20 Princeton undergraduates, and in this and the other experiments, we checked that they were naive about game theory. The instructions explained that the participants would be presented with simple games, and that their task was to decide which option they would choose in each game. Before the participants responded to each game, they were asked: Do you have all the necessary information to play the game? If *No*, what else do you need to know to make the decision? The participants then made a choice.

Results

The majority of the participants responded that they had the all the necessary information to play the game: only five participants requested their partners' payoffs on more than half the trials. Hence, the bias to play the games without knowing these payoffs was reliable (Sign test, $n = 20$, $p < .025$). There was no reliable difference between dependent games and independent games in the tendency for participants to play in ignorance of their partners' payoffs (15 participants in both cases played on more than half the trials; $F < 1$, $p > .25$). The preferred strategy was to maximize the maximum possible gain (14 out of 20 participants on more than half the trials, $p < .05$).

Experiment 2: Conditional descriptions of games

The previous experiment presented games in the form of payoff matrices. Skeptics could argue that this format is not familiar enough to naive participants to enable them to do justice to their ability. We therefore carried out a similar experiment, but each game was presented in a set of conditional assertions, which are easy to understand. For example, an independent game was described in the following way:

If you choose A and your partner chooses A, you will receive \$5.

If you choose A and your partner chooses B, you will receive \$6.

If you choose B and your partner chooses A, you will receive \$4.

If you choose B and your partner chooses B, you will receive \$5.

One group of participants received such descriptions, which are incomplete because they do not say anything about the partner's payoffs. A second group of participants received only partial descriptions of their own payoffs, e.g:

If you choose A and your partner chooses A, then you will receive \$5.

If you choose B and your partner chooses B, then you will receive \$6.

These descriptions were only for cases in which both players chose the same options (AA and BB). A third group of participants received descriptions of only their partner's payoffs but not their own, e.g.:

If you choose A and your partner chooses A, your partner will receive \$5.

If you choose A and your partner chooses B, your partner will receive \$6.

If you choose B and your partner chooses A, your partner will receive \$4.

If you choose B and your partner chooses B, your partner will receive \$5.

According to the principle of self-interest, the participants should be more likely to ask for their own payoffs than for the payoffs of their partners. The participants in each group were asked three questions: Would you play the game? Do you have all the necessary information to make a choice? If No, what else do you need to know to make your choice? The procedure and the 25 games were the same as those in Experiment 1. We tested ten Princeton undergraduates in each group.

Results

In the group that knew only their own payoffs, 100% of responses were decisions to play both dependent and independent games. In the group that knew only their own partial payoffs, 100% of responses were decisions to play both sorts of games. But, as predicted, in the group that knew only their partners' payoffs only 40% of the responses (4 participants on more than half the trials) were decisions to play the games. The difference between the three groups is significant, Kruskal-Wallis ($\chi^2 = 14.5$, $p < .001$). Hence, the majority of participants who had only their partners' payoffs refused to play the games without knowing their own payoffs. The participants' preferred strategy was to maximize their average payoff (80% of strategies, Binomial test, $p < .005$).

Experiment 3: Games with real opponents

The participants in the previous experiments might have played games without knowing their partners' payoffs because the games seemed artificial and unreal. We therefore carried out a replication of Experiment 2 in a way that was closer to real games. The participants played against real opponents and they could win real money. Each experimental session tested two participants at a time, who had not previously met. They were told that they would be playing a set of games against each other. And they then went to different rooms, and each participant received the instructions and carried out the games. The design and procedure were otherwise identical to Experiment 2. We tested 10 Princeton undergraduates in each group. The participants were told that the person who won the most nominal money in the games would enter a lottery with a possibility to win \$20.

Results

The step towards verisimilitude slightly enhanced performance, but the results otherwise replicated the previous experiment. Two participants who knew only their own payoffs requested additional information on more than half the trials. Five participants who knew only their opponents' payoffs requested additional information on more than half the trials. Nine participants who knew only their own partial payoffs requested additional information (but only about the rest of their own payoffs). The difference between the three groups was significant (Kruskal-Wallis $\chi^2 = 11.21$, $p < .005$). A planned comparison between those who knew their own payoffs and those who knew their opponents' payoffs was also significant ($z = 3.2$, $p < .03$). The participants' preferred strategy was again to maximize their average payoff (70% of participants, $p < .005$). Hence, on the whole, individuals who knew their own payoffs were happy to play with real partners and for real money.

Experiment 4: The effect of losses.

In the previous experiments, none of the games threatened the participants with a loss of money depending on the outcome of a game. People are known to think differently about losses than about gains. They are risk seeking when they think about losses but risk averse when they think about gains (Tversky and Kahneman, 1981). Gains and losses are represented asymmetrically. The negative effect of a loss of a certain amount is greater than the positive effect of a gain of the same amount. Hence, people may represent games with losses differently from the way they represent games with only gains. Likewise, losses may also affect individuals' strategic thinking. In particular, they might think more carefully and require more information about losses than they do when they think about gains. This greater care may, in turn, elicit a need for information about their partner's options and payoffs. A different possibility, however, is that potential losses would make individuals anxious and confused. Hence, they might represent less information than usual, and make even fewer requests for their partner's payoffs. To examine these possibilities, Experiment 4 used a set of games similar to those in the previous experiments, but it included payoffs that were losses. One group of participants played games with gains only in the first block of the experiment and games with gains and losses in the second block. Another group received the

two blocks in the opposite order. The procedure was similar to Experiment 3, using both real partners and a real monetary reward.

Results

The participants who received only gains in the first block were more likely to play in that block (97% of responses) than the group who received gains and losses in the first block (80% of responses in the first block, Kruskal-Wallis, $p < .005$). Overall, there was no difference between the first and second blocks in the propensity to play. But, the effect of loss in inhibiting participants from playing was greater in the second block than in the first block (Kruskal-Wallis $\chi^2 = 10.4$, $p < .05$).

Both groups were equally likely to request additional information (36% and 35% of responses). There was no significant effect of block. However, there was again a significant interaction between the group and the block, Kruskal-Wallis ($\chi^2 = 10.5$, $p < .05$). Only one participant who received only gains in the first block requested more information on more than half the trials; whereas six of the participants who received gains and losses in the first block requested more information on more than half the trials (Kruskal-Wallis $\chi^2 = 11.2076$, $p < .005$). Thus, the participants did not notice that something was missing when they played games with gains only. But, when they moved on to games with gains and losses, they tended to notice that the games were incomplete. In contrast, those who received games with gains and losses showed no change in their requests for additional information when they moved on to games with only gains (36% requests in the first block, and 36% requests in the second block). In sum, losses had their largest effects when they appeared after the games with gains only. The participants preferred strategy was again to maximize average payoffs (85% of strategies, $p < .005$).

General Discussion

Our everyday experiences often call for representing what other people think, believe and desire. Strategic decision making is one of many situations that call for individuals to think about their partners preferences and choices. Moreover, they often have to take into account their opponents considerations of their own options, and so on and on. This problem may easily become intractable, and, at the very least, highly complex. The present paper has defended

the principle of *self-interest*: when individuals have to think strategically, they tend to focus on their own options and payoffs. The experiments corroborated this principle. Experiment 1 demonstrated the effect with payoff matrices. Experiment 2 replicated it with conditional descriptions of games. Both Experiment 2 and 3 showed that individuals notice when their own payoffs are missing, and that they then request them. When their own payoffs are described only in part, they request information about the rest of their payoffs. Otherwise, they are prepared to play in ignorance of their partner's payoffs both for dependent and independent games. Experiment 4 showed that when participants can lose money depending on their choices, the majority of them were still prepared to play without asking for additional information. It is rational to play independent games in ignorance of your partner's payoffs or likely choice of option; but it is not rational to play dependent games in these circumstances.

Why don't individuals realize that they should ask for their partner's payoffs? The simplest game that elicits the need for strategic thinking is one in which two players each have two options. Such a game, however, calls for reasoners to hold in mind four separate possibilities in order to work out an optimal strategy. Four simple possibilities are known to be at the limit of typical adult competence in reasoning (Johnson-Laird and Byrne, 1991), and so it is natural for reasoners to focus on their own payoffs. This tendency, as we have shown, is influenced by experimental manipulations. We believe that if naïve individuals were given immediate payoffs after each game, and ran the risk of loss with sub-optimal choices, then they would soon realize the need to infer their opponents' likely choices. They should then be able to eliminate clearly dominated strategies in simple games. But, it is unlikely that they would be able to compute an equilibrium for more complex games — the number of possibilities would overwhelm the processing capacity of working memory. As our results imply, naïve individuals do not normally

envisage the payoffs of their opponents, and that is why they do not ask for this information. As the adage says, it is hard to put oneself into others' shoes. This difficulty can, in turn, lead to an erroneous choice of option in those cases in which the optimal choice depends on the choices of others.

Acknowledgements

This research was supported in part by a grant from the National Science Foundation (Grant BCS 0076287) to the second author to study strategies in reasoning. Implicit Learning of Serial Reaction Time Tasks: Connectionist vs. Symbolic Models

Ron Sun (rsun@cecs.missouri.edu)

Department of CECS, University of Missouri, Columbia, MO

Chris Terry (cterry@cs.ua.edu)

Department of Computer Science, University of Alabama, Tuscaloosa, AL

Abstract

This paper describes simulations of implicit learning experiments. It compares simulations using connectionist models with existing simulations using symbolic models. It addresses an interesting issue raised by proponents of symbolic models, namely, the claim that implicit learning is better modeled by symbolic rule learning programs. This paper revisits such an issue by quantitatively comparing connectionist simulations with symbolic ones, in the context of the serial reaction time task of Lewicki et al (1987). This comparison is interesting because it helps to clarify, to some extent, some long standing confusions compounded by many claims and counter-claims. It also points to the idea of hybrid connectionist and symbolic models.

Introduction

There have been a variety of simulations of implicit learning experiments. The majority of them are connectionist, while some are symbolic. Proponents of symbolic models, however, raised some interesting issues. They claim that implicit learning is "better modeled by symbolic rule learning programs" (Ling and Marinov 1994), and symbolic models are better for "not only conscious processing but also unconscious processing", based on some limited success of modeling Lewicki's experiments (Lewicki et al 1987) using C4.5, a decision tree learning algorithm developed by Ross Quinlan. In this paper, we will revisit such claims by quantitatively comparing connectionist simulations with symbolic ones, especially in the context of the serial reaction time (SRT) task of Lewicki et al (1987). This comparison is interesting because it helps to clarify, to some extent, some long standing confusions compounded by many similar claims and counter-claims.

Some background is in order here. With regard to the serial reaction time task specifically, Cleeremans and McClelland (1991) simulated an SRT task involving nondeterministic grammars. They employed a recurrent backpropagation network that saw one position at a time but developed an internal context representation over time that helped to predict next positions. The model succeeded in matching human data in terms of degrees of dependency on preceding

segments in a sequence (i.e., conditional probabilities). However, their success was obtained through introducing additional mechanisms for several types of priming (e.g., short-term weight changes and accumulating activations). They did not deal with capturing directly the reaction time data of their subjects.

Ling and Marinov (1994) simulated the SRT data from Lewicki et al (1987), using a symbolic decision tree learning algorithm (i.e., C4.5). Their model produced data on quadrant prediction accuracy and, based on the data, they succeeded in matching the human reaction time data, using a transformation that included a power function (for capturing unspecific learning). However, they did not attempt the match without such a power function.

Similarly, Lebiere et al (1998) simulated data on SRT using ACT-R. The simulation was based on a combination of instance-based learning implemented in ACT-R and a set of hand-coded, symbolic, a priori rules. A fit with data was found.

It has been claimed, on the connectionist side, that a vast majority of human cognitive activities (i.e., implicit processes), including "perception, motor behavior, fluent linguistic behavior, intuition in problem solving and game playing — in short, practically all skilled performance", can only be modeled by subsymbolic computation (connectionist models), and symbolic models can give only an imprecise and approximate explanation to these processes (Smolensky 1988). It has also been claimed, on the symbolicist side, that "one and the same algorithm can be responsible for conscious and nonconscious processes alike", or even that implicit learning "should be better modeled by symbolic rule learning programs" (Ling and Marinov 1994). See also Fodor and Pylyshyn (1988).

This argument is in a way similar to what has been happening in relation to modeling past-tense acquisition in children (including how to capture the U-shaped curves in the process). For arguments and counter-arguments concerning advantages or disadvantages of connectionist and symbolic models in relation to past-tense acquisition, see, for example, Christiansen et al (1999). In this paper, let us look into the simulation of implicit learning specifically.

Simulating Lewicki et al (1987)

The Model. CLARION is a general cognitive architecture capable of simulating a variety of cognitive data (see Sun 1999, Sun et al 2001). The model consists of two levels: an implicit learning level (the bottom level) that learns using trial-and-error processes through a combination of backpropagation and reinforcement learning (i.e., Q-learning) algorithms (Watkins 1989, Sun and Peterson 1998); an explicit learning level (the top level) that learns explicit rules through on-line hypothesis testing based on information from the implicit level (the bottom level), which was termed "bottom-up learning" in Sun et al (2001). Bottom-up learning proceeds by first constructing the most specific rule that corresponds to a "good" decision made by the bottom level, and then refining (generalizing) it through examining the result of applying the rule, mainly through the use of an "information gain" measure that compares the success ratios of various modifications of the current rule.

Note that for this type of task, there is no significant amount of explicit learning in human subjects, as shown by Lewicki et al (1987). (This point can be controversial; more discussions later.) Correspondingly, in the model, the top level is not relevant (practically speaking). A parameter in the model is set in accordance with domain characteristics, which prevents explicit learning from occurring. The parameter concerns the minimum frequency of repetitions of a pattern in order for the afore-mentioned explicit learning to occur (see Sun et al 2001 for details of explicit learning).

In the bottom level, a simplified learning process was employed, again in accordance with domain characteristics, in which the backpropagation algorithm was used but temporal credit assignment (Q-learning) was not. This was because in this task, subjects predicted one position at a time, with immediate feedback, and thus there was no role for temporal credit assignment (Q-learning) to play.

Specifically, in the model, $Q(x, a)$ computes the likelihood of the next position a , given the information concerning the current and past positions x . The actual probability of choosing a as the current prediction (of the next position) is determined based on the Boltzmann distribution, as is common for Q-learning:

$$p(a|x) = \frac{e^{Q(x,a)/\alpha}}{\sum_i e^{Q(x,a_i)/\alpha}}$$

where α controls the degree of randomness (temperature) of the decision-making process. This method is also known as Luce's choice axiom (Watkins 1989).

The error signal used in the learning algorithm is as follows:

$$\Delta Q(x, a) = \alpha(r + \gamma \max_b(y, b) - Q(x, a)) = \alpha(r - Q(x, a))$$

Figure 1: Identification trials and matrix scanning trials.

where x is the input, a is one of the outputs (the predictions), $r = 1$ if a is the correct prediction, $r = 0$ if a is not the correct prediction, and $\gamma \max_b(y, b)$ (which represents Q-learning of Watkins 1989) is set to zero because of the fact that only one-step prediction is involved in this task. This process amounts to a variant of the backpropagation algorithm. Based on the error measure, the backpropagation algorithm is applied to adjust internal weights (which are randomly initialized before training) as usual.

The Task. The task was based on matrix scanning: Subjects were to scan a matrix, determine the quadrant of a target digit (the digit 6) and respond by pressing the key corresponding to that quadrant. Each block consisted of six identification trials followed by one matrix scanning trial. In identification trials, the target appeared in one of the quadrants and the subject was to press the corresponding keys. In matrix scanning trials, the target was embedded among 36 digits in a matrix, but the subject's task was the same. See Figure 1. In each block of 7 trials, the actual location of the target in the 7th (matrix scanning) trial was determined by the sequence of the 6 preceding identification trials (out of which 4 were relevant). 24 rules were used to determine the location of the target on the 7th trial. Each of these rules mapped the target quadrants in the 6 identification trials to the target location on the 7th trials in each block. 24 (out of a total of 36) locations were possible for the target to appear. The major dependent variable was the reaction time on the 7th trial in each block.

The whole experiment consisted of 48 segments, each of which consisted of 96 blocks of 7 trials (so there were a total of 4,608 blocks). During the first 42 segments, the afore-mentioned rules were used to determine target locations. However, on the 43rd segment, a switch occurred that reversed the outcomes of the rule set: the upper left was replaced by the lower right, the lower left was replaced by the upper right, and so on. The purpose was to separate unspecific learning (e.g., motor learning) from prediction learning (i.e., learning to predict the target location on the 7th trial).

The Data. The reaction time data of three sub-

jects were obtained by Lewicki et al (1987). See Figure 2. Each curve showed a steady decrease of reaction times up until the switch point. At that point, there was a significant increase of reaction times. After that, the curve gradually lowered again.

The Model Setup. The input to the model contained (a sequence of) 6 elements, with each element having 4 possible values (for 4 different quadrants).¹ The output contained the prediction of the 7th element in a sequence. Thus, 24 input units (representing 6 elements, with 4 values each), 24 output units (one for each possible location of the 7th element of a sequence), and 18 hidden units were used. We tried various parameter settings. The best learning rate was 0.5, with a momentum term of 0.2. The model was trained by presenting the stimulus materials in the same way as the human experiment described by Lewicki et al (1987), without any further embellishments or repetitions of the materials.

Because in this experiment there were a total of 6^4 sequences with each consisting of 7 elements, the setting was too complex for subjects to discern the sequence structures explicitly, as demonstrated in human experiments by various explicit tests done by Lewicki et al (1987). Computationally, no explicit representation of knowledge could be extracted in the model, because the large number of sequences entailed that there were no sufficient repetitions of any particular sequence throughout the experiment, which prevented the model from coming up with any rule. The density parameter was set to be 1/50; that is, at least one repetition (of a sequence) was necessary every 50 blocks in order to maintain an explicit rule (Sun and Peterson 1998). In this task, there were 4,608 presentations of sequences and there were $6^4 = 1296$ different sequences, and thus on average the repetition rate of any sequence was only 0.0007716.

A note concerning the existence of explicit knowledge in implicit learning tasks in general is in order here. It has been hotly debated whether there is a significant amount of explicit knowledge involved in implicit learning tasks and whether explicit knowledge can account for the performance in such tasks (see Sun et al 2001, 2002 for reviews). Without getting into details of such debates, we can reasonably believe that, although explicit knowledge may be present in many implicit learning tasks, the existence of a significant amount of such knowledge is highly unlikely in the task of Lewicki et al (1987), given the complexity of their task setting (Sun et al 2002). This was the assumption made in our simulation, although it would not change our main points even if this assumption was dropped.

The Match. We were able to create an error rate curve going downwards (averaged over 10 runs to

Figure 2: Matching Lewicki's data using linear transformation. See Figure 4 for parameter values.

ensure its representativeness), resembling Lewicki et al's reaction time curves. The model reached 100% accuracy at a point before the switch. See Figure 3. The question is how we should translate the error rates into reaction times.

One way of translation is through a linear transformation from error rates to reaction times (as commonly used in existing simulation work); that is, $RT_i = a * e_i + b$, where RT_i is the reaction time (in ms), e_i is the error rate, and a and b are two free parameters. For each set of human data, we adjust the parameters to match the data. One possible interpretation of linear transformation is that it specifies the time needed by a subject to search for a target item as well as the time needed by a subject to respond to a target item without searching (through correctly predicting its location); that is,

$$RT_i = ae_i + b = b(1 - e_i) + (a + b)e_i$$

where b is interpreted as the time needed to respond to an item without searching (since $1 - e_i$ is the probability of successfully predicting the location of a target item), and $a + b$ is interpreted as the time needed to respond to an item by first searching for it and then responding to it (after finding it). So, instead of relying on additional functions (as in e.g. Ling and Marinov 1994), this method relies only on error

¹A sequence of 6 elements was assumed to be within the capacity of the short-term working memory.

rates to account for human performance in terms of reaction times.

Another way of generating reaction time from prediction accuracy is through a formula used by Ling and Marinov (1994):

$$RT_i = t_1(1 - e_i) + t_2e_i + B\alpha^{-t}$$

where t_1 is the time needed to respond when there is no search (using correct predictions), t_2 is the time needed to respond when search is necessary, B is the initial motor response time, and α is the rate at which the motor response time decreases. The third term is meant to capture unspecific practice effects (mostly resulting from motor response learning). In other words, in this formula, we separate the motor response time from the search time and the prediction time (as represented by t_1 and t_2 respectively). Note that, if we set $B = 0$, we have $t_1 = b$ and $t_2 = a + b$ and thus this equation becomes the same as the previous one. This formula takes into account the independent nature of motor learning, as separate from the learning of prediction of target locations. However, it involves two more free parameters.

Using the linear transformation (without the power function), we generated three sets of data from the error rate curve reported earlier,² one for matching each human subject in Lewicki et al (1987), using different a and b values for each subject.³ As shown in Figure 2, the model outcome fit the human data well up to the point of switching (segment 42). When the switch to a random sequence happened, the model's reaction times became much worsened whereas the subject's reaction times suffered only slightly (although in a statistically significant way).⁴

²When curve fitting, we used Microsoft Excel Solver to find the best parameter values (e.g., a and b in $a * x + b$) such that the difference between the model data and the subjects data was minimized. Microsoft Excel Solver uses the Generalized Reduced Gradient nonlinear optimization algorithm.

³The error rate curve reported earlier was the best curve and happened to match all three subjects approximately equally well after the transformation (with different parameters for each subject). Note that Ling and Marinov (1994) also used a single error rate curve to match different subjects with different parameters for transformation.

⁴We tried many different parameters but discovered that the size of the jump tended to vary little (unless the match as a whole was bad). It is clear, from our experiments with different settings of the parameters, that, if the model learns the sequences perfectly before the switch (as is the case with our model), the model data inevitably have huge jumps. However, the more of the sequences it does not learn, the flatter the curve and the less the jump. Although this may model Subjects 1 and 3 satisfactorily, Subject 2 has a large drop in reaction time early on which is best matched by having the model increase its accuracy in a rapid manner.

Figure 3: The model prediction errors.

Subject 1:	$a = 320$	$b = 430$
Subject 2:	$a = 860$	$b = 620$
Subject 3:	$a = 170$	$b = 530$

Figure 4: Parameters for matching Lewicki's data.

Next, we added the power function, in order to compare our simulation with Ling and Marinov (1994). After adding the power function, we re-fit the parameters. The effect of adding the power function was that we reduced the contribution from the model prediction (i.e., the error rate e_i) while we took into consideration the contribution from the power function. In this way, we obtained a much better match after the switch and a good match before the switch at the same time.⁵ See Figure 6. Note that in the figure, we used exactly the same parameter settings (for a, b, B , and α) as in Ling and Marinov (1994). These parameters might be further optimized, which led to a slightly better fit but the difference was not significant.

The match between our model and the human data was excellent as measured by the sum-squared errors. Compared with Ling and Marinov (1994), CLARION (with the power function) did better on two of the three subjects, using the same parameters for transformation as Ling and Marinov did. See Figure 7 for a comparison.

So, what conclusion can we draw concerning the relative merits of the two models? The next section attempts to answer this question in a more theoretically oriented way.

Connectionist vs. Symbolic Models

Revisiting the argument of whether connectionist or symbolic models are better models (see Introduction), what do the above simulations have to say about it? To put it simply, we believe that this issue is a red herring. Being able to simulate some limited

⁵By adding the power function, we were able to reduce the total difference between the jumps in our curves and the corresponding jumps in the subject data by half. This comparison suggested that the amount of benefit the human subjects got from their predictions (i.e., by lowering e_i) was, although significant, relatively small. Significant benefit was gained through the improvement of motor responses as represented by the power function.

Subj.1:	$t_1 = 150$	$t_2 = 350$	$B = 700$	$\alpha = 0.33$
Subj.2:	$t_1 = 150$	$t_2 = 350$	$B = 1600$	$\alpha = 0.33$
Subj.3:	$t_1 = 100$	$t_2 = 210$	$B = 800$	$\alpha = 0.19$

Figure 5: Parameters for matching Lewicki's data with power functions added (as in Ling and Marinov 1994).

Figure 6: Matching Lewicki's data with power functions added. See Figure 5 for parameter values.

data of implicit learning amounts to very little, in that any Turing equivalent computational process, that is, any generic computational model, should be able to simulate these data. Thus, the simulation of data by itself does not prove whether a particular model is a suitable one or not (cf. Roberts and Pashler 2000). Other considerations need to be brought in to justify a model.

We would suggest that one such issue is accessibility (Sun 1995, 1999, Cleeremans et al 1998). While symbolic models of implicit learning lead to explicit symbolic representation of implicit knowledge (e.g., Ling and Marinov 1994, Lebiere et al 1998, Anderson 1993) that is evidently accessible (without using any add-on auxiliary assumptions), connectionist models of implicit learning lead to implicit (subsymbolic, distributed) representation of knowledge that is in-

model	subj.1	subj.2	subj.3
CLARION w/o power f.	0.30	1.85	0.14
CLARION w/ power f.	0.07	0.25	0.05
Ling & Marinov (1994)	0.14	0.43	0.04

Figure 7: Comparing the goodness of fit in terms of SSEs.

herently inaccessible (such as in the bottom level of CLARION).

Note that it is generally not the case that distributed representations (as in the bottom level of CLARION) are absolutely inaccessible, but they are not as immediate as localist representations. Distributed representations may be accessed through indirect, transformational processes. As Kirsh (1990) put it, "explicitness [of representation] really concerns how quickly information can be accessed..... It has more to do with what is present in a process sense, than with what is present in a structural sense". The accessibility difference between the two levels should be understood in this way.

Thus, connectionist models have a clear advantage: Being able to match human implicit learning data (at least) as well as symbolic models, they also account for the inaccessibility of implicit knowledge better and more naturally than symbolic models (Cleeremans et al 1998, Sun 1999). In this sense, they are better models.

On the other hand, it is generally agreed upon that symbolic/localist models have their roles to play too. They are better at capturing explicit processes, including their accessibility (Smolensky 1988, Sun 1995, 1999).

This contrast lends support to the belief that, since connectionist models are good for implicit processes and symbolic models for explicit processes, the combination of the two types should be adopted in modeling cognition (Sun 1995, 1999). There have been many philosophical and psychological theories related to this point (Sun et al 2001): See, e.g., James (1890), Schacter (1987), Reber (1989), Stanley et al (1989), Clark and Karmiloff-Smith (1993), and Sun (1999). This combination is exemplified by the CLARION model (Sun et al 2001).

This combination may also shed some light on the issue of consciousness, because the implicit/explicit difference involves, in its core, the issue of awareness, which is the key to consciousness (Cleeremans et al 1998). The representational distinction provides a plausible grounding for the notion of awareness (see Sun 1999 for details of theoretical arguments).

Simulating Other Tasks

Beside modeling the data from Lewicki et al (1987), CLARION has also been applied to model a variety of other SRT experiments, including Curran and Keele (1993) and Willingham et al (1989). Notably, in

these tasks, due to sufficient repetitions of sequential patterns, explicit learning of these patterns was involved, although implicit learning was dominant. Therefore, the top level of CLARION was utilized. Together, the model demonstrates the interaction between implicit and explicit learning (Sun et al 2002).

Beside SRT simulations, CLARION can capture data from many other implicit learning tasks. These tasks include artificial grammar learning (Reber 1989) and process control (Stanley et al 1989) (see Sun et al 2002). In addition, CLARION has also simulated extremely complex skill learning tasks as well, such as the minefield navigation task (see Sun et al 2001). The generality of CLARION has been amply demonstrated, on top of its cognitive validity.

Detecting the Local Maximum: A Satisficing Heuristic

Abstract

In a simulated yard sale task, participants were asked to sell a series of objects, each of which would attract three customers making a randomly determined offer. Participants were told to maximize the total "take" from the sale. The analysis of the data revealed that high-performing naïve participants were using a strategy that made them relate the current event to the seemingly irrelevant preceding events. We argue that this strategy is consistent with Simon's (1982) notion of "satisficing heuristic", which accounted for both participants' limited computation capacity and the task environment.

Introduction

Intuitive predictions and probabilistic judgments are often used as tasks to evaluate people's performance in judgment and decision-making research, and a common scheme is to collect incorrect predictions and misjudgments by "setting up a 'trap' that subjects would fall into if they were using a particular heuristic" (W. Goldstein & Hogarth, 1996, p.26). In this type of research, predictions derived from probability theory are often used as an objective criterion, and violations of the normative models are labeled as biased or irrational. Tversky and Kahneman's "heuristics and biases" program has been the most influential in this field. They suggested that intuitive predictions and judgments are often mediated by a small number of distinctive mental operations, which they called *judgmental heuristics*. "These heuristics ... are often useful but they sometimes lead to characteristic errors or biases" (Kahneman & Tversky, 1996, p.582). For example, people's tendency to use a small sample of preceding events to evaluate an overall process was attributed to a "representativeness" bias (Tversky & Kahneman, 1973). This bias has been used to account for many cognitive behaviors, such as the tendency to see streaks in random sequences (Gilovich, Vallone & Tversky, 1985), and failure to "acquire a proper notion of regression" (Tversky & Kahneman, 1973). In a recent study on gambling behaviors, Thaler & Johnson (1990) concluded that "current choices are often evaluated with the knowledge of the outcomes which have preceded them, (but) such knowledge can often be a handicap" (p.643).

However, the heuristics and biases research program has recently been controversial, partly because "biases" sometimes appear highly adaptive. Thus, Tweney &

Doherty (1983) argued that confirmatory tendencies ("confirmation biases") can be adaptive when hypotheses are relatively new and untested. Further, in an extensive series of studies, Gigerenzer and his colleagues (e.g. 1991, 1994, Gigerenzer & Todd, 1999) found evidence which led them to strongly disagree with Kahneman and Tversky. They argued that many seemingly naïve "fast and frugal heuristics" are adaptive in an uncertain environment. Similarly, Kareev, et al., suggested that the limited capacity of working memory (hence the use of small samples) could actually help the early detection of covariation since small samples of correlated variables are highly skewed (Kareev, 1995; Kareev, Lieberman & Lev, 1997).

The present study followed Simon's (1982) notion of "bounded rationality", which takes into account both people's limited computation capacity, and the structure of task environments. Our findings suggest that under circumstances when the precise prediction derived from statistics or probability theory is not the only criterion, heuristics based on a small sample size can be valuable. With a *satisficing* strategy that only needs to "look for a satisfactory alternative" (Simon, 1982, p.295), naïve participants were able to effectively accomplish the goal of the task, based on the evaluation of a few preceding events.

Recognizing the Maximum of a Sequence

The statistical properties of sequential lists of evidence have long been of interest to mathematicians. The dowry problem (or the secretary problem) is a classic example in the dynamic programming literature, one analyzed by Cayley in 1875 (see Ferguson, 1989). As a mathematical problem, the dowry problem is difficult to solve, requiring advanced mathematical knowledge and problem solving ability. Obviously, few, if any, people are likely to work out the exact stopping point mathematically in an everyday life situation when a similar problem is encountered. Instead, without complicated calculations, a player might need to use "common sense" to make decisions. The present study adopted a simplified version of the problem – a simulated "yard-sale" task – to test how naïve people evaluate preceding events and make decisions when facing sequential events generated by an unknown process.

Participants were asked to sell a series of objects in a simulated yard sale. Each object attracted three potential buyers, each of whom came at a different time and made a

different offer. It was explained that offers that were rejected would not return, so that the task was to guess which was the best offer, and to take it when available.

Imagine that a person is selling a used car, and that visitors with different offers come up in a random order. After 5 offers have been declined in a week, a visitor comes in with a price higher than any of the previous ones. Another 5 offers will probably take another week and by then this car must be sold. Whether to stop waiting and grab the currently available offer then depends on how satisfied the car owner feels about the current offer. The only information available to evaluate the current situation is the previous encounters. Probably, "common sense" would tell this car owner to take the offer now, because future offers might not get better.

This is in effect a *satisficing heuristic* (Simon, 1990), which is a strategy that only needs to "look for a satisfactory alternative" (Simon, 1982, p.295), as suggested by the notion of bounded rationality. The strategy also fits the category of fast and frugal heuristics suggested by ecological rationality, because it makes "a choice from a set of alternatives encountered sequentially when one does not know much about the possibilities ahead of time" (Gigerenzer & Todd, 1999, p.13).

We show that in at least one situation – when the random process that generates offers is independently and identically distributed – this satisficing strategy is *optimal*. Let R_i denote the offer at time i , where $i = 0$ is the current offer, -1 is the previous one, $+1$ is the next one, and so on. Assume the car owner has encountered m R 's (from R_{-1} to R_{-m}) and found that R_0 is the best one so far. If he actually chooses it, because R_0 now is the biggest number in a local sequence of $(m + 1)$ numbers, in the long run, the value of such R_0 has a good chance to be higher than the population mean. For a continuous distribution from 0 to 1, the expected value of such R_0 is $(m+1)/(m+2)$. Further, R_0 might just be a good stopping point because the potential gain from the following n offers after R_0 might not have a good chance to get better. To see this, let A denote the event that R_0 is higher than its previous m offers, and B denote the event that R_0 is higher than its following n offers. Then two prior probabilities can be described as

$$p(A) = p(R_0 > R_{-1}, \dots, R_{-m}) = 1/(m+1)$$

$$p(B) = p(R_0 > R_1, \dots, R_n) = 1/(n+1)$$

And the conditional probability can be calculated as

$$p(B|A) = p(AB)/p(A) = (m+1)/(m+n+1)$$

Note that, with a fixed n , $p(B|A)$ approaches to an asymptote of 1 as m increases. That is, with an appropriate m (after considering a certain number of offers), the car owner can make a better decision than a random guess. For example, when $m = 5$, $n = 5$, $p(B|A)$ is $6/11$, and this favors selling. To take the message of $p(B|A)$ in another way, it has suggested a *stopping point*, because the coming n offers do not have a good chance to get better.

Two Optimal Strategies for the Yard Sale Task

With the development above, we can easily determine the optimal strategy for the yard sale task. Suppose there is only

one trial in the task (only one object for sale). Let P_1 denote the first offer, P_2 the second and P_3 the third. Before knowing any of the three offers, the prior probability for each offer to be the best is equal:

$$p(P_1 \text{ is best}) = p(P_2 \text{ is best}) = p(P_3 \text{ is best}) = 1/3$$

Note that knowing the exact value of P_1 does not change this probability. With a random guess, the chance of hitting any of the three possible prices is $1/3$. However, if we skip P_1 and consider P_2 , the conditional probability is no longer equal. If P_2 is higher than P_1 , we should take it immediately because $p(P_2 > P_3 | P_2 > P_1) = 2/3$. Otherwise, we should take P_3 . A pay-off matrix (Table 1) shows that the optimal strategy (Option B*) is to always skip P_1 . If P_2 is better than P_1 , accept P_2 ; if P_2 is worse, choose P_3 . This strategy increases the chance of hitting the best offer to $1/2$, with a $1/3$ chance of hitting the middle price, and a $1/6$ chance of hitting the lowest one. For convenience, we will refer to this strategy as the "one deal strategy".

Table 1: The pay-off matrix for the seller

Option	Rank orders of offers						Total
	LMH	MHL	LHM	MLH	HLM	HML	
A	-1	0	-1	0	1	1	0
B*	0	1	1	1	0	-1	2
C	1	-1	0	-1	-1	0	-2

Note: L is the lowest price, M the middle, H the highest. "LMH" means that the lowest price comes first, and so on.

Option A: always choose P_1 (random guess).

Option B*: choose P_2 if $P_2 > P_1$, otherwise choose P_3 .

Option C: choose P_2 if $P_2 < P_1$, otherwise choose P_3 .

Gains: the seller gains -1 when hitting the lowest offer; 0 for the middle offer; 1 for the highest offer.

However, in a real-life situation, decisions are rarely made in temporal isolation. Thus, as in a common scheme in laboratory experimental settings, our yard sale task used repeated trials to collect multiple data points from each individual participant. This fact had a significant impact on the optimal strategy. Recall that the single deal strategy assumes that in each deal, the order in which three offers appear is completely independent from any other events, and requires that the first offer always be ignored. What if the first offer actually is the best one? With the information from the preceding trials, we can actually evaluate how good the first offer is. Calculating an optimal strategy for deals in a sequence is very complicated because it needs to specify a distribution of three offers for each deal. However, when distributions of offers in several deals within a local sequence are similar, as an approximation, the principles we presented above can be generalized. In our experiment, we set the basic price for each object to range from \$50 to \$100, with a maximum random fluctuation of $\pm \$16$. Figure 1 shows the overall distribution of these offers.

Figure 1 The distribution of offers. $N = 5760$, x-axis is price, y-axis is proportion.

The satisficing principle suggests that the offers for previous objects (in previous trials) can be used to predict whether you are getting a good offer for the next item. In other words, when you are considering a first offer for a table, if you can recall that the last several visitors, who were seeking other items, were not as generous as the current customer, you may want to sell the table right now. It seems quite against a researcher's intuition that a normative strategy would predict that previous offers for an umbrella will help to predict the current offers for a table, especially when one thinks that the umbrella deal is "over", and the two deals should be independent. The answer to this counter-intuitive puzzle is that the independence is only partial. While the order in which different offers come out for each deal is independent, the values of these offers, if they are in the same or similar distributions, regress to the population mean.

There are two ways to evaluate the first offer for a given trial. The "local count strategy" is based upon a count of the number of previous low offers. That is, if the current first offer is higher than a certain number of previous offers (for other items), take it. The optimal strategy depends on the specific distribution of the random offers and the payoff matrix. In our specific experimental setting, we used computer simulations and found that the best number of comparisons was 6. A modification of the local count strategy, the "moving average strategy" compares the current offer with the average of previous several offers. We reasoned that participants might not remember the exact values of the previous offer but might still have a vague memory of the overall average in a short local sequence. A logistic regression over simulated data showed that in our experiment setting, the value difference of the first offer for a given item from the mean of the previous 6 offers (for the other two items), is significant as a predictor of whether the first offer is the best among all three offers: $\chi^2(1, N = 1888) = 191.03, p < .01$. That is, as this difference increases, this first offer is more likely to be the best of the three.

With this background, we were ready to find out whether participants are good at detecting good offers when they actually appear, and whether they use information from previous encounters to help their current decision-making.

Method

Participants were 15 undergraduate students from an introduction to psychology class at Bowling Green State University, none of whom had taken a course on game theory or probability theory. We refer to them as novice participants. One graduate student with extensive experience in judgment and decision-making and related research also participated, and will be referred as the expert participant.

The task was conducted using a self-paced computer program. Each participant completed 120 trials (the number of objects to be sold). One object was to be sold in each trial. Participants could take any of the three offers at the time it was available, but could not go back to an earlier declined offer. Once an offer was taken, offers thereafter were not presented. The third offer was forced if the first two were rejected by the participant, and this was the only case when participants knew exactly if they had hit the best out of three offers. After each trial, participants were given a confirmation that the object was sold at the price they selected. Participants' choices and their total earnings were recorded. An average experiment session lasted about 25 minutes.

Results

Overall Performance To evaluate participants' overall performance, we ran a simulation 5000 times using each of the three strategies: a random guess (randomly choosing one of the three offers), the "single deal strategy" and the "local count strategy". Each time the simulation sold 120 items using the actual selling list that was used in the experiment. In the local count strategy, the first offer for each item was compared with 6 previous offers (which were for the preceding items¹). It was accepted when it was the highest in the comparison. Otherwise, it was declined and the single deal strategy was applied. Table 2 shows the simulation results and the actual participant data.

Table 2 Comparisons between human participants and 3 simulations

Group	N	Mean Score (95% confidence interval)	Std Dev.
Random Guess	5000	8889.8 \pm 2.0	72.74
Single Deal Strategy	5000	9160.7 \pm 2.1	75.54
Local count Strategy	5000	9277.7 \pm 3.4	121.22
Human Participants	16	9196.0 \pm 31.0	58.15

Note that all 16 participants received a score that was at least 1.5 SD above the mean of the random guess simulation.

¹ When an offer was taken before all offers were presented, the number of items whose offers were being compared may exceed 2.

Each participant's score was then compared to the result as if the single deal strategy had been applied to his/her actual selling list. Ten participants' scores were higher than the result of the single deal strategy. Using the standard deviation resulting from the single deal strategy simulation (75.54), four participants' scores were at least 1.5 SD above the score resulting from the single deal strategy. We will refer to these four as the "outstanding participants".

Strategy Use We looked at participants' choice patterns in regard to their consistency with the optimal strategies, at three steps when each offer was being considered. The following three choices are consistent with the optimal strategies (single deal or multiple deals):

C1. Accept the 1st offer if it is better than several previous offers (for other items).

C2. Decline the 1st offer, and accept the 2nd offer if it is better than the 1st one.

C3. Accept the 3rd offer if the 2nd is worse than the 1st.

C2 and C3 are equivalent to the single deal strategy, now separated into two parts. All three choices above are consistent with the local sequence strategy. Since choices at the 3rd offer were forced, whether participants' actual choices were consistent with the optimal strategies could be looked at whether they had met or violated the conditions at C1 and C2. Note that the single deal strategy actually forbids C1. Specifically, C1 can result from considering the count of the previous low offers (the local count strategy) or the value difference of the first offer compared to the mean of the previous offers (the local average strategy), and we tested them separately.

Of all 16 participants, only the expert participant found the single deal strategy, and followed C2 and C3 consistently. The 15 novice participants, by contrast, often violated either C2 or C3 or both. However, to a significant extent, their choices did follow C1. For each individual novice participant, we ran a logistic regression, using the value difference of the first offer from the mean of the previous 6 offers, to predict the participant's acceptances of the first offers. Of the 15 participants, 11 showed significant results at a 0.01 level. On the group level, the result is also significant: $\chi^2(1, N=1770) = 304.69, p < .01$. This indicates that the novices were at least partly using the moving average strategy.

Since the one deal strategy is a subset of the local count strategy, we combined the 16 participants' reactions on all three offers to see if their behaviors were consistent with the local count strategy. Table 3.1 and Table 3.2 show that they did show such consistency when the previous 1 or 6 offers were compared to the current offer. That is, if the offer being considered was better than all of the previous 1 or 6 offers, participants were more likely to accept it. Otherwise, they were more likely to decline it. This finding was consistent with the local count strategy.

Table 3.1 Compared to previous 1 offer

	Worse	Better	Total
Decline	1773	952	2725
Accept	616	1424	2040
Total	2389	2376	4765

$$\chi^2 = 580.177, p < .01$$

Table 3.2 Compared to previous 6 offers

	Worse	Better	Total
Decline	2397	328	2725
Accept	1553	487	2040
Total	3950	815	4765

$$\chi^2 = 114.140, p < .01$$

All of the 4 "outstanding participants" were novice participants. However, they actually outperformed the expert participant and the one deal strategy. They were different from the other 11 non-expert participants in that their behaviors were consistent with one of the requirements of the one deal strategy (C2 and C3), although not both. Their gains on the first offers when these offers were the best had offset the losses from violations of the condition of C2.

Learning across Trials In a study of the Monty Hall dilemma, Granberg & Dorr found that participants showed signs of learning across trials under certain conditions. In our study, we also looked at whether there were systematic changes in participants' choices across trials. Specifically, we suspected that participants might have learned the specific distribution of random offers in earlier trials, so that, in later trials, they only needed to recognize "globally big numbers" instead of applying their heuristics independently and locally. For example, an offer of \$116 might have been the best one for an item sold in an early trial. If participants had this number memorized, they might just pick an offer of \$116 or higher in a later trial, no matter when this offer was presented (whether it was the 1st, 2nd, or 3rd offer). If this were the case, "big wins" might have been over-represented in terms of participants' uses of simple heuristics.

However, in our experimental setting, each item's 3 offers varied around its own basic price. Although these basic prices could be close, there was no way to tell that \$116 was the best offer for item A only because it had been the best offer for item B. In other words, recognizing "big numbers" alone would not help in optimizing the total performance. In fact, when we partitioned each participant's 120 trials into 3 blocks with 40 trials each, we did not find any significant differences across blocks, indicating that learning was probably not important across trials.

Discussion

None of the 15 novice participants found and consistently used the one deal strategy. We reasoned that this was because finding and consistently applying this strategy required participants to use background knowledge in probability theory, and they simply did not have this training. Their consistency with the local sequence strategy explained why they had good performances. This does not suggest that they actually did the calculation and found the correct mathematical solution, because this would require even more knowledge and computational capacity, not to mention that it was within a short experiment session. However, as we suggested before, it is not necessary for a person to work out the correct mathematical proof to use the local sequence strategy. Such a strategy could arise from participants' everyday life experiences, from which they had learned a simple satisficing heuristic: "grab any good chance when you can".

Surprisingly, the outstanding performers actually outperformed the expert participant who found and consistently applied the one deal strategy. This was because the one deal strategy has to give up all opportunities of accepting the first offers when they were the best. One reason that prevented the expert participant from finding the local sequence strategy might have been that the everyday life heuristic had been "blocked" by his knowledge of probabilistic judgment research. This finding is very similar to Goldstein and Gigerenzer's (1999) "less-is-more" effect, that relative ignorance can actually benefit a decision maker. By isolating the previous encounters from the current decision-making situation, the expert participant had to search the infinite probability space again, and previous experience, either beyond or within the experiment task, could not help.

In their 1973 paper, Kahneman and Tversky suggested that "people do not acquire a proper notion of regression, ... they do not expect regression in many situations where it is bound to occur", because "regression effects typically violate the intuition that the predicted outcome should be maximally representative of the input information". On the contrary, the finding in this study that participants' behaviors were consistent with the local sequence strategy, indicated that people do have good intuitions about such regression, and can also take advantage of it.

We argue that to evaluate naïve people's probabilistic judgment and decision-making, one has to take into account both people's limited computation capacity and the task environment. One obvious message of the task was that, if we had used the single deal strategy as the *only* criterion, we might have concluded that participants were being irrational, and would then have to face the puzzling evidence that they actually performed very well. Instead, the results suggest that the advantages of the satisficing principle are important and cannot be ignored. By using these strategies, people can benefit from their own experiences, even from a small sample of preceding events.

Top-Down versus Bottom-Up Learning in Skill Acquisition

Ron Sun (rsun@cecs.missouri.edu)

Xi Zhang (xzf73@mizzou.edu)

Department of CECS, University of Missouri, Columbia, MO 65211, USA

Abstract

This paper studies the interaction between implicit and explicit processes in skill learning, in terms of top-down learning (that is, learning that goes from explicit to implicit knowledge) vs. bottom-up learning (that is, learning that goes from implicit to explicit knowledge). Instead of studying each type of knowledge (implicit or explicit) in isolation, we highlight the interaction between the two types of processes, especially in terms of one type giving rise to another. The work presents an integrated model of skill learning that takes into account both implicit and explicit processes and both top-down and bottom-up learning. We examine and simulate human data in the Tower of Hanoi task. The paper shows how the quantitative data in this task may be captured using either top-down or bottom-up approaches, although top-down learning is a more apt explanation of the human data currently available. The results demonstrate the difference between the two different directions of learning (top-down vs. bottom-up), and also provide a new perspective on skill learning in the Tower of Hanoi task.

Introduction

This paper studies the interaction between the implicit and explicit processes in skill learning. It explores two directions of skill learning: top-down learning and bottom-up learning. Top-down learning goes from explicit knowledge to implicit knowledge, while bottom-up learning goes from implicit knowledge to explicit knowledge. Instead of studying each type of knowledge (implicit or explicit) in isolation, we want to highlight the interaction between the two types of processes, especially in terms of one type giving rise to another.

In this work, we want to test possibilities of bottom-up learning vs. top-down learning. We do so by using the task of Tower of Hanoi, which is arguably a typical benchmark problem in high-level cognitive skill acquisition and has been used in many previous studies of skill acquisition, cognitive modeling, and cognitive architectures (see, e.g., Proctor and Dutta 1995, Anderson 1993, Anderson and Lebiere 1998).

To explore bottom-up and top-down learning, the work presents an integrated model of skill learning that takes into account both implicit and explicit

processes and both top-down and bottom-up learning, although the model was initially designed as a purely bottom-up learning model. We examine and simulate human data in the Tower of Hanoi task. The work shows how the quantitative data in this task may be captured using either top-down or bottom-up approaches, although we will show that top-down learning is a more apt explanation of the human data currently available in this task.

Overall, the result of our simulations suggests that both directions are possible in human cognitive skill acquisition, and the actual direction may be either bottom-up or top-down (or a mix of both), depending on task settings, instructions, and other variables. These results demonstrate the two different directions of learning (top-down vs. bottom-up), and also provide a new perspective on skill learning.

Top-Down vs. Bottom-Up: The CLARION Model

The role of implicit learning in skill acquisition and the distinction between implicit and explicit learning have been widely recognized in recent years (see, e.g., Reber 1989, Stanley et al 1989, Willingham et al 1989, Anderson 1993, Seger 1994, Proctor and Dutta 1995, Stadler and Frensch 1998). However, although implicit learning has been actively investigated, complex and multifaceted interaction between the implicit and the explicit and the importance of this interaction have not been universally recognized. To a large extent, such interaction has been downplayed or ignored, with only a few notable exceptions (e.g., Mathews et al 1989, Sun et al 2001). Similar oversight is also evident in computational simulation models of implicit learning (with few exceptions such as Cleeremans 1994 and Sun et al 2001).

Despite the lack of studies of interaction, it has been gaining recognition that it is difficult, if not impossible, to find a situation in which only one type of learning is engaged (Reber 1989, Seger 1994, Sun et al 2001). Our review of existing data has indicated that, while one can manipulate conditions to emphasize one or the other type, in most situations, both types of learning are involved, with varying amounts

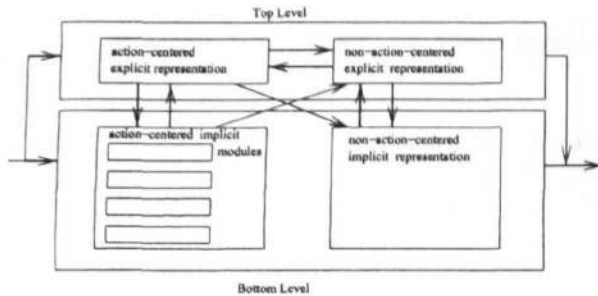

Figure 1: The CLARION architecture.

of contributions from each.

Empirical demonstrations of interaction can be found in Stanley et al (1989), Willingham et al (1989), Bower et al (1990), Wisniewski and Medin (1994), and Sun et al (2001). These demonstrations used a variety of means, including experimental manipulations such as verbalization, explicit instructions, and dual tasks.

Likewise, in the development of cognitive architectures (e.g., Rosenbloom et al 1993, Anderson 1993, Anderson and Lebiere 1998), focus has been mostly on "top-down" models (that is, learning first explicit knowledge and then implicit knowledge on the basis of the former). The bottom-up direction (that is, learning first implicit knowledge and then explicit knowledge, or learning both in parallel) has been largely ignored, paralleling and reflecting the related neglect of the interaction of explicit and implicit processes in the implicit learning literature.

However, there are a few pieces of work that did demonstrate the parallel development of the two types of knowledge or the extraction of explicit knowledge from implicit knowledge (e.g. Willingham et al 1989, Stanley et al 1989; see also Karmiloff-Smith 1986, Mandler 1992), contrary to usual top-down approaches in developing cognitive architectures.

To tackle these issues, we developed the model CLARION (Sun and Peterson 1998, Sun et al 2001). CLARION is an integrative model with a dual representational structure. It consists of two levels: the top level encodes explicit knowledge and the bottom level encodes implicit knowledge. See Figure 1. In this paper, we will focus only on action-centered components of the model.

Overall Action Decision Making

1. Observe the current state x .
2. Compute in the bottom level the "value" of each of the possible actions (a_i 's) in the state x : $Q(x, a_1), Q(x, a_2), \dots, Q(x, a_n)$.
3. Find out all the possible actions (b_1, b_2, \dots, b_m) at the top level, based on the the current state information x (which goes up from the bottom level) and the existing rules in place at the top level.

4. Choose an appropriate action a , by combining (in some way) the values of a_i 's (at the bottom level) and b_j 's (which are sent down from the top level).
5. Perform the action a , and observe the next state y and (possibly) the reinforcement r .
6. Update the bottom level in accordance with an appropriate algorithm (to be detailed later), based on the feedback information.
7. Update the top level using an appropriate algorithm (for constructing, refining, and deleting rules, to be detailed later).
8. Go back to Step 1.

The Bottom Level

Representation The input to the bottom level consists of three groups: (1) sensory input, (2) working memory items, (3) the top item of the goal stack. The output of the bottom level is the action choice. It consists of three groups of actions: working memory set/reset actions, goal push/pop actions, and external actions. These three groups are computed by separate networks.

Learning The *Q-learning* algorithm (Watkins 1989) is a reinforcement learning algorithm. In the algorithm, $Q(x, a)$ estimates the maximum (discounted) cumulative reinforcement that can be received from the current state x on. The updating of $Q(x, a)$ is based on:

$$\Delta Q(x, a) = \alpha(r + \gamma e(y) - Q(x, a)) \quad (1)$$

where γ is a discount factor, y is the new state resulting from action a in state x , and $e(y) = \max_b Q(y, b)$. Note that x and y include sensory inputs (internal and external), working memory items (if any activated), and the current goal (if exists).

Q-learning can be implemented in backpropagation networks (Sun and Peterson 1998). Applying *Q-learning*, the training of the backpropagation network is based on minimizing the following error at each step:

$$err_i = \begin{cases} r + \gamma e(y) - Q(x, a_i) & \text{if } a_i = a \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

where i is the index for an output node representing the action a_i , and a is the action performed. Based on the above error measures, the backpropagation algorithm is applied to adjust internal weights (which are randomly initialized before training).

The Top Level

Representation At the top level, in contrast to the bottom level (which involves distributed representation due to the use of backpropagation networks), explicit knowledge may be captured in computational modeling by a symbolic or localist representation, in which each unit is easily interpretable and has a clear conceptual meaning, i.e., a semantic label. This characteristic captures the property of

explicit knowledge being accessible and manipulable (Sun 1995). Explicit knowledge is expressed in the form of rules.

The condition of a rule, similar to the input to the bottom level, consists of three groups: sensory input, working memory items, and the current goal. The output of a rule, similar to the output from the bottom level, is an action choice. It may be one of the three types: working memory actions, goal actions, and external actions.

Bottom-Up Learning The *Rule-Extraction-Refinement* algorithm (RER) learns explicit rules using information in the bottom level (to capture the bottom-up learning process). The basic idea of this algorithm is as follows: If an action decided by the bottom level is successful (i.e., if it satisfies a certain criterion), then the agent extracts a rule (with its action corresponding to that selected by the bottom level and with its condition specifying the current state), and adds the rule to the top-level rule network. Then, in subsequent interactions with the world, the agent refines the extracted rule by considering the outcome of applying the rule: If the outcome is successful, the agent may try to generalize the condition of the rule to make it more universal; if the outcome is not successful, then the condition of the rule should be made more specific and exclusive of the current state.

The way we measure the successfulness of an outcome (which is based on an information gain measure) and the way generalization/specialization is carried out (which is based on adding/removing allowable input values) have been fully described in Sun and Peterson (1998) and Sun et al (2001). Due to lengths, we will not repeat the details here.

Fixed Rules Some of the rules at the top level may be fixed. This type of rule (FR) represents genetic pre-endowment of an agent presumably acquired through evolutionary processes, or prior knowledge acquired from prior experience.

FRs enable top-down learning. With these rules in place, the bottom level learns under the guidance of the FRs. Initially, the agent relies mostly on the FRs in its action decision making. But gradually, when more and more knowledge is acquired by the bottom level through observing actions directed by FRs, the agent becomes more and more reliant on the bottom level (given that the cross-level combination is adaptable). Hence, top-down learning takes place.

Combining the Two Levels

In P_{RER} percent of the steps, if there is at least one RER rule indicating a proper action in the current state, we use the outcome from that rule set; in P_{FR} percent of the steps, if there is at least one fixed rule indicating a proper action in the current state, we use the outcome from that rule set; otherwise, we use the outcome of the bottom level. These probabili-

Condition/No. of disks	2	3	4	5
No verbalization	0.0	2.1	4.3	21.2
Verbalization	0.0	0.0	0.9	1.3

Figure 2: The RT data of Gagne and Smith (1962).

ties are adaptable based on "probability matching" (with two parameters; Sun and Peterson 1998).

When we use the outcome from the top level, we randomly select an action suggested by the matching rules. When we use the outcome from the bottom level, we use the stochastic decision process for selecting an action: $p(a|x) = \frac{e^{Q(a,a)/\alpha}}{\sum_i e^{Q(a,a_i)/\alpha}}$, where x is the current state, a is an action, and α controls the degree of randomness (temperature) of the decision-making process.

Experiments

Tower of Hanoi

In the Tower of Hanoi task of Gagne and Smith (1962), there were three pegs. At the beginning, a stack of disks was stored on one of the pegs. The goal was to move these disks to another (target) peg. Only one disk can be moved at a time from one peg to another. These disks were of different sizes, and larger disks could not be placed on top of smaller disks. Initially, the stack of disks was arranged according to size so that the smallest disk was at the top and the largest was at the bottom.

Subjects were given 3-disk, 4-disk, and 5-disk versions of the task in succession, each version running until a final stable solution was found, and their mean numbers of moves (and excess moves) were recorded. Some subjects were instructed to verbalize: They were asked to explain why each move was made. The performance of the two groups of subjects (verbalization vs. no verbalization) was compared. In this task, we intend to capture the verbalization effect on performance.

Figure 2 shows the performance of the two groups in terms of mean number of excess moves (in excess of the minimum required number of moves in each version). Comparing the verbalization group and the no verbalization group in the figure, the advantage of verbalization is apparent. ANOVA indicated that there was a significant difference between verbalization and no verbalization ($p < 0.01$).

There have also been data concerning the response time of each move made by human subjects in this task. For example, the RT data from Anderson (1993) were obtained under the special instructions to subjects that encouraged a goal recursion approach (Anderson 1993). Data were available for the cases of 2, 3, 4, and 5 disks (Anderson 1993).

Bottom-Up Simulation

The Model Setup. To implement bottom-up sim-

ulation, we set up the following: (1) For deciding on each type of action (external, goal stack, or working memory actions), there is a corresponding network and a set of RER rules, respectively. (2) The input to each network is the same, including sensory input, the top goal stack (GS) item, and working memory (WM) items. (3) The outputs of the networks are external actions, GS actions and WM actions, respectively. (4) At each step, if the actions are decided by the top level, we use the existent RER rule set to get three actions—external, GS or WM actions; if the actions are decided by the bottom level, we use Boltzmann distribution to select an action from the output of each network. (5) The chosen action are coordinated and performed, and the top level and the bottom level are updated then.

During the simulation of the verbalization group, we changed the parameters for probability matching in cross-level combination to reflect the heavier reliance on the top level by the verbalization group.

Strictly speaking, GS is not necessary. But we include GS, because of generality, and because it may help learning sometimes (but it may also hamper learning sometimes). The format of GS is not important. For our simulation, each GS item includes both a subtower and a focal disk:

```

DSIZE: Size of SUBTOWER
FROM: Current peg of SUBTOWER
TO: Target peg of SUBTOWER
DSIZE1: Size of FOCAL-DISK
FROM1: Current peg of FOCAL-DISK
TO1: Target peg of FOCAL-DISK

```

A subtower is a set of disks at the top of a peg. The focal-disk is the disk beneath a subtower. Note that this set of information is redundant.

Multiple goal items could be stored in the GS one on top of another. Whenever a goal item is achieved, it will be popped.

A simple set of possible goal recursion rules is as follows (Anderson 1993):

```

If DSIZE > 0, then push a new goal for moving a subtower of
size DSIZE-1 to the spare peg and for moving the disk of size
DSIZE to its target peg.
If DSIZE = 0, then make a move of FOCAL-DISK to its target
peg.
If LOC(SUBTOWER)=TO and LOC(FOCAL-DISK) ≠ TO1,
then move FOCAL-DISK to its target peg.
If LOC(SUBTOWER)=TO and LOC(FOCAL-DISK)=TO1,
then pop the current goal.

```

Such a set of rules was hand-coded into the model in the ACT-R simulation of Anderson (1993). However, in this simulation, we did not use such hand-coded, a priori rules in the model. We want the model itself to learn something that has essentially the same effect (in both the bottom level and the top level through bottom-up learning).

The Match. The result of our simulation is shown in Figure 3. 20 runs (simulated subjects) were included in each group. Analogous to the analysis of the human data, ANOVA (number of disks × verbalization vs. no verbalization) indicated that

Condition/No. of disks	2	3	4	5
No verbalization	0.0	1.6	3.2	10.5
Verbalization	0.0	0.4	0.9	2.5

Figure 3: The bottom-up simulation of Gagne and Smith (1962).

in the model data, there was likewise a significant main effect between verbalization and no verbalization ($p < 0.01$), confirming the verbalization effect we discussed.

We compared this bottom-up simulation with a *bottom-only* simulation. We noticed that the bottom-only simulations consistently failed to learn, even when given 10 times as much training trials. This contrast suggests the importance of top-level explicit knowledge and bottom-up learning. Without them, the task was hard to learn. This fact is consistent with our synergy hypothesis (see Sun and Peterson 1998, Sun et al 2001): The reason why there are these two distinct levels (implicit and explicit) is because of the synergy that may be generated from the interaction of the two levels. The interaction of the two levels helps to improve learning, and facilitate performance and transfer (Sun et al 2001).

However, both the bottom-up and the bottom-only simulation failed to capture the RT data reported earlier.

Top-Down Simulation

The top-down simulation of the Tower of Hanoi task involves the use of fixed rules, along the line of Anderson's (1993) model, but adds the involvement of the bottom level (implicit processes), which may interfere with the top-level fixed rules. Therefore, compared with Anderson's, this is a far more complex simulation, using a more complete model that involves both explicit and implicit knowledge.

The Model Setup. Specifically, in this simulation, fixed rules were used, which implemented Anderson's (1993) analysis of subjects' performance of this task as a subset. That is, we first implemented the previous set of rules (Anderson 1993), as fixed rules at the top level of CLARION. However, this simulation was a lot more complex than top-level only (rule-based only) simulations because we had to deal with the interference from the bottom level, as the bottom level was running in parallel with the top-level rules but might recommend different actions and thus interfere with the top-level goal recursion process. The main change lied in the process of popping a sequence of goals from the GS, when a move made by the bottom level was not consistent with the top goal in the GS. In that case, we kept popping goals until reaching a goal on the GS that was consistent with the move or until the GS was empty. The structure of the GS was the same as before. The

implemented set of fixed rules was an extension of the previous set. Due to their lengths, we will not show them here.

In the bottom level, Q-learning was used. Due to the use of fixed rules, Q-learning was under the "guidance" of the top level in this case. Therefore, top-down learning was involved in this case.

For capturing the performance of the verbalization subjects, the parameters for probability matching in cross-level combination were adjusted to reflect their tendencies to rely more heavily on the top level.

The Match. The result, comparing verbalization vs. no verbalization, is shown in Figure 4. 20 runs (simulated subjects) were included in each group. Analogous to the analysis of the human data, ANOVA (number of disks \times verbalization vs. no verbalization) indicated that in the model data, there was likewise a significant main effect between verbalization and no verbalization ($p < 0.01$), confirming again the verbalization effect we discussed.

In this simulation, we further tackled the capturing of the RT data from Anderson (1993), which incidentally included only a portion of the total moves in each case. The data were obtained under the special instructions to subjects that encouraged the goal recursion approach (as embodied by the fixed rules used in the top level of CLARION).

Figure 5 shows the data. The comparisons between the human and the simulation data were presented for the cases of 2, 3, 4, and 5 disks. In the data, there is a regular pattern of RT peaks, which arguably reflect planning periods during which goal recursion (establishing a sequence of subgoals to be accomplished) happens (Anderson 1993).

As demonstrated by Figure 6, it is clear that the response times of the two simulated groups were reasonably close to the human data (where there was no distinction between verbalization and no verbalization). Although the match of both groups were excellent, the match between the simulated verbalization group and the human data were closer.

This particular simulation shows that the CLARION framework can accommodate traditional accounts of human performance in this task (such as Anderson 1993, Anderson and Lebiere 1998). Moreover, it extends such accounts by incorporating implicit processes (at the bottom level) as well as explicit processes (at the top level). The role of the bottom level in this task (and other high-level cognitive skill tasks) is that of "quick-and-dirty" reactions that may lead to bad performance initially due to interference with top-level rule-guided actions, but may also lead to faster and better performance given sufficient training.

The account of human RT data is important, because such an account has been viewed as the hallmark of a successful simulation. We succeeded in showing that the two-level framework of CLARION can capture the essential patterns of the human RT

Condition/No. of disks	2	3	4	5
No verbalization	0.00	1.50	4.90	12.55
Verbalization	0.00	0.25	0.90	2.65

Figure 4: The top-down simulation of Gagne and Smith (1962).

Figure 5: Simulation of the response time data of Tower of Hanoi from Anderson (1993). Four cases are included. The verbalization group is used.

data, which further testifies to the cognitive validity of the model.

Discussions

Along with the simulations of other tasks (see Sun et al 2001), we fully demonstrated that CLARION is capable of both bottom-up and top-down learning, although it was initially developed as a purely bottom-up learning model. The original reason for developing a bottom-up learning model was that in the existing literature, bottom-up learning has been very much ignored as argued by Sun and Peterson (1998) and Sun et al (2001), and therefore, there is a real need to counter-balance this bias. Our bottom-up learning model, since then, has been successful in accounting for a wide variety of skill learning tasks in a bottom-up fashion, ranging from serial reaction time tasks (sequence learning tasks), to minefield navigation tasks (Sun et al 2001). But one lingering question has been: Can this same model account for top-down learning? The present work answers this question clearly in the affirmative: CLARION can not only account for bottom-up learning data, but also

the verbalization group:		
	MSE	relative MSE
2-disk	0.002	0.001
3-disk	0.529	0.107
4-disk	0.252	0.098
5-disk	1.555	0.299
overall	0.967	0.200

the non-verbalization group:		
	MSE	relative MSE
2-disk	0.222	0.049
3-disk	0.086	0.024
4-disk	0.579	0.109
5-disk	3.271	0.375
overall	1.925	0.236

Figure 6: The MSEs and the relative MSEs of the RT simulations of Tower of Hanoi.

top-down learning ones. And it accounts for top-down learning equally well.

Our experiments in the TOH task showed that top-down learning is a more plausible way of accounting for the existing human data in this task. This does not come as a surprise. The task structure of TOH is highly structured, with inherent recursive embedding, and involves a small number of input/output dimensions. These characteristics naturally lead to explicit processing. This tendency is even further exacerbated by the instructions that explicitly encourage goal recursion strategies.

Abstract

We present experimental evidence from a study in which we monitor eye movements as people respond to pre-recorded instructions generated by a human speaker and by two text-to-speech synthesizers. We replicate findings demonstrating that people process spoken language incrementally, making partial commitments as the instruction unfolds. Specifically, they establish different referential domains on the fly depending on whether a definite or indefinite article is used. Importantly, incremental understanding is observed for **both** natural speech instructions and synthesized text-to-speech instructions. These results, including some suggestive differences in responses with the two text-to-speech systems, establish the potential for using eye-tracking as a new method for fine-grained evaluation of dialogue systems and for using dialogue systems as a theoretical and experimental tool for psycholinguistic experimentation.

Background

Rapid increases in the accuracy and speed of automatic speech recognition and the increased availability of off-the-shelf text-to-speech systems has fueled great interest in spoken dialogue systems (e.g., Allen, Byron, Dzikovska, Ferguson, Galescu & Stent, 2001; Zue, Seneff, Glass, Polifroni, Pao, Hazen & Hetherington, 2000). As the sophistication of such systems increases, we can expect applications to more open-ended domains with larger vocabularies and more varied utterance types. The feasibility of such systems raises both applied and theoretical issues for work on natural language processing that crosses disciplinary boundaries. We focus on two issues here. The first, a computational issue, addresses the need for developing better evaluation tools for dialogue systems, especially tools that can evaluate comprehension on an utterance-by-utterance and within-utterance basis. The second, a psycholinguistic issue, is the possibility that in the near future implemented dialogue systems could serve as a

powerful tool for developing and testing psycholinguistic models by allowing stimuli to be generated 'on the fly,' conditioned on the current state of the discourse.

A necessary prerequisite for enabling both of these goals is that people respond to synthesized speech in much the same way as they do to natural speech. We present experimental evidence from a study in which we monitor eye movements as people respond to pre-recorded instructions generated by a human speaker and by two text-to-speech synthesizers. We replicate findings demonstrating that people process spoken language incrementally, making partial commitments as the instruction unfolds. More specifically, listeners establish referential domains on the fly depending on whether a definite or indefinite article is used.

Eye movements as an evaluation tool

Spoken utterances unfold over time, resulting in a stream of temporary ambiguities. For example, as the instruction *Click on the beaker* unfolds, the word *beaker* is briefly consistent with multiple candidates, including *beetle*, *beeper*, and *speaker*. Numerous psycholinguistic studies demonstrate that people comprehend utterances continuously, entertaining multiple lexical candidates (e.g., Marslen-Wilson, 1987), making provisional commitments at points of syntactic ambiguity, and resolving reference incrementally (e.g., Altmann, 1998; Tanenhaus & Trueswell, 1995). Recent studies using eye movements to a task-relevant object in a visual workspace as people follow spoken instructions provide striking evidence for both incremental understanding and rapid integration of multiple constraints (Tanenhaus, Spivey-Knowlton, Eberhard & Sedivy, 1995; 1996; Tanenhaus, Magnuson & Chambers, forthcoming). For example, if the instruction *Click on a beaker* is presented in a context in which there are two icons of beakers and two icons of beetles, then reference will be delayed until the word *beaker* is disambiguated phonetically

(Allopenna, Magnuson & Tanenhaus, 1998). However, if there is only a single beetle, then reference will be speeded because the indefinite article *a* implies that there should be multiple referents – a condition met by the beakers but not by the beetle. Similarly, reference resolution for *Click on the beetle* will be facilitated because the beetle is the only icon that is unique. However, if the alternatives do not satisfy the uniqueness conditions associated with the article, e.g., if there is only one beaker and two beetles, and the instruction is *Click on a beaker*, then listeners are temporarily confused, looking first at the beetles before clicking on the beaker (Hanna, 2001).

If such incremental behavior carries over into recognition of synthesized utterances, then it should be possible to develop evaluation measures that can track the temporary commitments listeners make as they are processing utterances. This could establish a new evaluation methodology for speech synthesis and dialogue systems that could provide much more fine-grained information than is possible with existing techniques. This is particularly important for evaluating the quality of speech synthesis because crucial information about potential reference resolution, such as the form of an article, is carried by monosyllabic unstressed words that exhibit considerable variability with local phonetic context, as well as the overall prosodic environment of an utterance. Eye-tracking measures are good potential candidates for such an evaluation methodology because they can be incorporated into natural tasks and are well suited for any application in which the user is working within a visual workspace. The present study explores the feasibility of using eye tracking for this purpose by examining (a) whether processing is incremental when instructions are generated from a text-to-speech system and (b) whether such investigations might reveal subtle problems with synthesized speech that could impair real-time performance in natural tasks involving reference resolution.

Dialogue systems as a psycholinguistic tool

There is a growing awareness in the psycholinguistic community of the importance of examining real-time processing in natural tasks using conversational language. The advent of head-mounted eye tracking has begun to make such investigations possible. However, the field is currently facing both a theoretical and a methodological challenge. The long-term theoretical challenge is that we need theories of discourse processing that can incorporate the notion of a rich, dynamic context that characterizes the type of knowledge that listeners and speakers bring to bear on real-time interactive conversation. We suggest that practical dialogue systems, that is, dialogue systems in which participants focus on a specific task such as tutoring or problem solving, are the right grain to provide such models, if they are modified to address real-time generation and understanding. The shorter-term methodological challenge is that we need methods of generating utterances on the fly based on the current state of the discourse, in

order to allow testing of alternative hypotheses, by presenting trials on which, for example, an inappropriate referential expression is used. Such trials cannot be plausibly generated by a confederate speaker, nor is it feasible to use pre-recorded instructions in any but the simplest experiments. We believe that it will soon be possible to use practical dialogue systems for this purpose. However, a crucial precondition is to determine whether listeners do indeed process synthesized utterances incrementally.

Experiment

The current experiment was intended as an initial investigation of the utility of using eye movements to evaluate spoken dialogue systems and using text-to-speech utterances in psycholinguistic experiments. We addressed the following question: Would listeners use the presence of an indefinite article compared to a definite article to differentially circumscribe potential referents as an expression unfolds? We addressed this question by examining eye movements within displays containing a pair of identical shapes and two unique shapes, using instructions such as *Click on the/a square*. Previous research with experimenter-generated instructions demonstrates that listeners assume that a definite article introduces a uniquely describable referent, whereas an indefinite article assumes that more than one referent meets the referential description (Chambers, Tanenhaus, Eberhard, Filip & Carlson, in press; Hanna, 2001).

Method

Fifteen members of the University of Rochester community were paid for their participation in this study. All participants were native speakers of English and had normal or corrected-to-normal vision. In the experimental trials, participants saw a visual display (described below) and heard an auditory instruction (one of three voice conditions) directing them to click on one of the objects on the screen. We used a within design, so each participant heard all three voice conditions (synthesizer 1, synthesizer 2 and the human voice), which were counterbalanced across experimental trials. The auditory stimuli were generated using two commercially available text-to-speech synthesizers and a digitally recorded human voice. For the human voice auditory stimuli, each instruction sentence was read aloud by an adult male volunteer and recorded with a TASCAM portable DAT recorder. The recorded voice instructions were then digitized using the SoundEdit 16 program. All auditory stimuli were minimally adjusted digitally so that the critical noun phrases were comparable in length for all three voices.

Eye movements were monitored using a lightweight head-mounted pupil/corneal reflection tracking system (ISCAN, model RK-726PCI). Calibration was monitored throughout each trial, and adjustments were made between trials if necessary. The experimental materials were presented with the PsyScope 1.0 program on a Power

Macintosh 7100/66 with a 15" color monitor.

During the experimental session, participants were seated at a comfortable distance from the computer monitor. For each trial a grid (Figure 1) appeared on the screen. The participant then clicked on the bull's eye in the center of the grid to hear the auditory instruction, e.g., *Click on the heart*, which began playing 2000 ms after the mouse click. When the participant clicked on the target object the grid was replaced by a white screen with the printed instruction *Click here for the next trial* in a random location on the screen.

Figure 1: Sample trial screen for the experiment

Each person participated in 24 such trials, 8 in each speech condition. The voice conditions were counterbalanced across experimental trials in three lists. The order of the voice condition was pseudo-randomized so that the same voice would occur in no more than two consecutive trials. Half of the trials involved a definite noun phrase, e.g., *Click on the heart*, and half involved an indefinite noun phrase, e.g., *Click on a square*. The definite and indefinite articles were never used infelicitously – shapes referred to with an indefinite article were always duplicated and shapes referred to with a definite article were always unique.

Results

Participants clearly made use of information about definiteness when comprehending both human and synthesized speech. Recall that the display contained four objects: two were identical (duplicated) and two were unique. For a definite instruction one of the unique objects was the target. For an indefinite instruction, the participant could select either of the duplicated shapes. For instructions with definite articles (e.g., *Click on the heart*) participants were more likely to look at the unique distractor than either of the duplicated distractors ($F(2)=310.38$, $MSE=7.34$, $p<.01$), and there was no interaction with voice type. For instructions with indefinite articles (e.g., *Click on a square*) participants were more likely to look at either of the

duplicated items than at the definite distractors ($F(1)=117.52$, $MSE=10.29$, $p<.01$). Again, there was no interaction with voice type.

Let us first consider the trials with instructions containing definite articles. Figure 2 shows the proportion of looks over time to the target, the unique unrelated item, and the two duplicate unrelated items in the trials with a definite article for the human voice condition. The zero point on the x-axis corresponds to the onset of the noun phrase, e.g., *the heart*. Participants clearly use the definiteness information carried by the article because looks to the duplicate unrelated items subside approximately 100 milliseconds before the target is distinguished from the unique unrelated item. Thus the items that are consistent with the definite article are first disambiguated from the items that are not consistent with the definite article, and then the target is disambiguated from the unrelated item.

The data from the two synthesized voice conditions follow the same general pattern. Specifically, the disambiguation between unique and duplicated items (i.e., definite vs. indefinite) occurs approximately 100 milliseconds before the two unique items (i.e., definite target vs. definite unrelated) are disambiguated in each of the synthesized voice conditions.

There is, however, an important difference between the human and the synthesized voice conditions – the disambiguation points occur later in the synthesized voice conditions than in the human voice condition (Figure 3). This difference is not due to differences in the length of the articles in the three voice conditions – we have verified that these did not differ.

Figure 2: Results from the human voice condition: Proportion of looks to all items for definite instructions

One explanation for this difference could be that participants have greater difficulty understanding the synthesized voices. During debriefing, all participants reported that they had heard at least two distinct voices during the experiment, and at least one of these voices was

readily identifiable as synthetic.

We evaluated this hypothesis more formally by conducting a simple voice judgment survey. A new group of 16 participants listened to the auditory stimuli without the visual context and wrote down what they thought they heard for each trial. We compared their responses to the intended speech and found no differences in accuracy between the voice conditions for the definite instructions – in fact performance was at ceiling for all definite instruction auditory stimuli except one. In contrast, we observed large differences in accuracy for the indefinite instructions ($F = 6.43$, $p < .01$). The average accuracy for the human voice was 80%, while the accuracy scores for the synthesized voices were 65% for synthesizer 1 and 31% for synthesizer 2. This suggests that the delay in reference resolution for synthesized definite instructions may be due to distributional characteristics of the voices over the course of the interaction. We will return to this issue after examining the results for the indefinite instruction trials.

Figure 3: Proportion of looks to target (unique) and unique unrelated items for definite instructions

Now let us consider the trials with instructions containing indefinite articles. Figure 4 shows the average proportion of looks over time to the target (duplicate) items and the unrelated (unique) items for each of the three voice conditions during the trials with indefinite instructions, e.g., *Click on a square*. Note that in the indefinite condition, either of the duplicated items is an appropriate target in response to the spoken instruction. For clarity of presentation, looks to either of the indefinite targets are summed together and represented as a single line for each of the voice conditions in Figure 3. Similarly, looks to either of the unrelated (unique) items are summed together in a single line for each voice. Again, the zero point on the x-axis corresponds to the onset of the noun phrase, e.g., *a square*.

For all voice conditions, looks to the duplicated items diverge from looks to the unique items at roughly the same point. We cannot tell from this data whether these eye

movements are due to processing of the indefinite article or whether they are due to processing of the noun. It is surprising that we do not see differences in the time course of looks between the voice conditions, given the differences in accuracy for the voice judgement survey, but an examination of looks to the two duplicated items may provide an explanation.

Figure 4: Average proportion of looks to target (duplicate) and unrelated (unique) items for indefinite instructions

Figure 5: Proportion of looks to the target (duplicate) items chosen and not chosen for indefinite instructions

Figure 5 shows the proportion of looks over time to the two possible target items. For each voice condition the item identified as “chosen” is the duplicated item that the participant eventually clicked on and the item identified as “not chosen” is the other duplicated item.

For instructions in the human voice condition, participants considered each of the duplicated items before clicking on one, reflecting the expected circumscription of referential

domain in the indefinite condition. For instructions in the synthesized voice conditions, participants tended to click on the first of the duplicated items that came to their attention, reflecting a more restricted referential domain than expected – one more appropriate to a definite article interpretation.

These results demonstrate that participants make different assumptions about the felicity of the use of the article for the synthesized speech instructions than for the natural speech instructions, due to global differences in how well the indefinite articles could be understood in the three voice conditions. This could also explain the delays in disambiguation for the definite article instructions.

Implications

People process spoken language continuously, even though continuous recognition entails resolving numerous temporary ambiguities on the fly. We have shown that this mode of recognition carries over to speech that is clearly identifiable as computer-generated artificial speech. The results suggest that this paradigm can be used to provide a fine-grained evaluation of comprehension during human-computer dialogue. Specifically, during reference resolution, listeners use cues such as definiteness that are often carried by short unstressed words that are difficult to synthesize. Lack of clarity in synthesizing these words may interfere with reference resolution. While perhaps not a problem in such simple tasks as these, we can expect it to be more problematic in more complex applications, and as the global characteristics of the speech cause interactions with additional error sources, such as unnatural prosodic cues. The important point here, however, is that the eye-tracking technique can reveal even subtle comprehension problems at a fine degree of temporal resolution. This suggests that the same technique could be used to evaluate components such as those affecting lexical choice, sentence structure, intonation and even higher-level discourse intentions. In addition, the eye-tracking paradigm may provide a valuable new method of comprehension evaluation in multimodal language applications using visual displays.

Moreover, our finding that people naturally process synthesized speech incrementally means that computational dialogue-based systems have the potential to be a psycholinguistic tool, especially for experimental questions where it is important to be able to generate utterances on the fly. By using such systems, we could generate more complex stimuli than is possible using a confederate or pre-recorded speech. While there remains much to be done to make this a reality, the range of experiments it would enable is great.

Abstract

In this paper we argue that in order to resolve the controversy in Second Language Acquisition research concerning whether or not direct instruction is needed for second language acquisition, we need to use a broader sense of 'consciousness' than is used by second language researchers. Block's classification of consciousness into Access and Phenomenal consciousness seems promising. We associate Phenomenal consciousness with explicit knowledge and suggest that explicit instruction is useful. It enhances linguistic competence.

Introduction

This paper addresses a question that is of great importance for Second Language Acquisition (SLA) research. The question is 'what should the role of consciousness in second language (L2) acquisition be?' It is important to answer this question in order to resolve one of the biggest debates in the field of SLA, namely whether or not direct instruction is necessary or even valuable in L2 acquisition.

SLA researchers interested in consciousness should start by considering what others have to say about it. This is necessary to develop a comprehensive picture of consciousness. The debate in SLA needs to be informed by an adequate notion of what consciousness is. Only in this way can we reach an adequate view about its role.

One place to start is to consider what is said about consciousness in philosophy. We will start by comparing the different definitions of consciousness used by SLA researchers and by philosophers. Next we will introduce the controversy over whether L2 learners need to be conscious of grammar rules to learn the target language. Then we will examine Block's well-known distinction between access (A) consciousness and phenomenal (P) consciousness and where language, or more specifically second language, fits into this categorization. With this, we might be one step closer to understanding the role of consciousness in L2 learning/acquisition.

Issues and Positions

Definition(s) of Consciousness

How do SLA theorists and philosophers think about consciousness? As it turns out, quite differently. Let us look at some of the similarities and differences.

When SLA theorists talk about consciousness, they use the term in a quite narrow sense. Schmidt (1995), for example, points out that there are three different senses of the term 'consciousness' as it is used in SLA theory: levels of perception, noticing, and understanding. By contrast, philosophers have a broader understanding of the term. According to Clark (2001), the possibilities include wakefulness, self-awareness, availability for verbal report, availability for control of intentional action, and qualia.

To determine if all these terms are discussing the same, complex entity, they need to be further defined. If one desires to apply concepts of one discipline to another (philosophy to SLA in this case), this is something that we need to know.

According to Schmidt, 'levels of perception' could be defined as levels of a process of obtaining and perhaps processing information. Schmidt defines 'noticing' as rehearsal in short-term memory, while by 'understanding' he refers to rule understanding, i.e., grasping the meanings of rules and becoming thoroughly familiar with them.

Definitions of the terms from Clark's list of possibilities might go as follows: wakefulness is defined as a state in which we are sensitive to our surroundings and in which we can process incoming information and respond to it appropriately. Self-awareness he defines as a capacity to represent ourselves and to be conscious of ourselves 'as distinct agents'. Availability for verbal report is the capacity to access our own inner states and to describe them using natural language, while qualia concerns how things feel to us.

From the above, one can conclude that SLA theorists take consciousness to be something narrower than philosophers

believe. Perception and wakefulness may refer to (or be contained in) the same aspect of consciousness, while noticing and understanding could be seen as part of availability for verbal report. However, self-awareness and qualia are missing from the SLA picture of consciousness. Yet in second language learning (SLL) and acquisition, self-awareness and qualia may play an important role. It is well known that language is closely associated with consciousness in the broader understanding that we find in Clark and other philosophers. If so, this broader notion of consciousness needs to be considered by SLA theorists. We will return to this topic. For now, let us simply note that SLA researchers use a narrow notion of consciousness.¹

Consciousness and SLA

Next we want to consider a group of related issues: the role of consciousness in various SLA theories the debate in SLA and L2 pedagogy about its proper role, the role of Universal Grammar (UG) in L2 acquisition, and the respective roles of implicit and explicit learning in SLA.

According to Robinson (1996), current debate in SLA is centred on the role of consciousness in L2 development. This controversy is centred in turn on the question of whether or not grammatical instruction is effective for L2 acquisition and if so what kind of grammatical instruction is best. There are researchers who argue that grammatical instruction has only minimal effect on L2 acquisition, Krashen (1981) for example. According to him, L2 development is largely an unconscious process. Krashen does allow that there are two processes involved in L2 development, a conscious process of learning and an unconscious process of acquisition. The conscious process of learning is a system based on rules and their application, while the unconscious process of acquisition is a system responsible for language production. According to Krashen, conscious learning is limited to a small set of simple rule-governed domains. By contrast, development of the much more substantial acquired system is fostered by avoiding instruction and the provision of L2 rules. In his view, learners only have to be exposed to comprehensible language input in order to acquire grammar.

On the other side, there are researchers who argue that comprehensible input alone is not enough for optimal acquisition of the different aspects of grammar and that conscious grammatical instruction is necessary if learners are to have the data they need to acquire grammar (Strozer, 1994). In particular, Schmidt (1994) argues that consciousness of input at the level of noticing is a necessary condition for L2 development. Many other researchers support this view. They use terms such as focus-on-form (Long, 1994), consciousness-

raising (Ellis 1993, Fotos and Ellis 1991, Rutherford, 1987), and input-enhancement (Sharwood Smith, 1991). In one way or another, all of these terms are about directing learners' attention to grammatical form in order to help them internalize the L2 system. According to these researchers, teaching should include opportunities for learners to focus on form and consciously notice features of the L2 they are learning.

Universal Grammar and L2 Acquisition

It might appear that because there is little or no need for conscious instruction in L1 acquisition, there is little or no need for it in L2 acquisition either. However, it is well known that the two processes are quite different from one another. Let us compare the two in terms of the theory of Universal Grammar (UG).

According to Chomsky (1980), all of us have an innate capacity for language and we cannot choose not to learn language. We have a mental faculty for language that simply 'grows' as any other organ of our body grows. All that we need is a triggering cause, namely, a language environment. For L1 acquisition, little or no direct teaching is needed.

According to Flynn (1996), the theory of UG does not make any direct claims about L2 acquisition. However, it is important to know whether or not L2 learners in the process of L2 acquisition have access to UG. Ellis (1997) points out that different theories deal with this issue differently. However, there is some good evidence for the a Partial Access Hypothesis, which holds that only the parameters of UG that are common to L1 and L2 are accessible to an L2 learner. According to this view, an L2 learner needs to learn everything else by using general problem-solving strategies. If this is so, there is clearly room for direct conscious instruction in L2 learning.

Explicit and Implicit Knowledge and SLA

It is obvious that in L2 acquisition, both explicit and implicit learning are present. But that is not the same thing as direct conscious instruction being *necessary* for L2 learning. Nor does it say anything about the effects of each type of learning. So let us look these two kinds of learning and their connection(s) to consciousness. Before we enter this inquiry, let us define the two types of knowledge that these two types of learning yield.

According to Ellis, explicit knowledge is "the L2 knowledge of which a learner is aware and can verbalize on request", while the implicit knowledge is "the L2 knowledge of which a learner is unaware and therefore cannot verbalize." (Ellis, 1997, 139). We can report explicit knowledge, while we are not aware of implicit knowledge.

Hulstijn and Graaff (1994) attempt to determine to what

¹ It is important to mention that the above are not the only definitions of consciousness in either discipline. However, they are the most common ones.

extent SLA and acquisition of implicit knowledge can be assisted by explicit learning (instruction). According to them, learning varies from spontaneous discovery by a learner to explicit instructions by a teacher. They argue that in fluent speakers, knowledge of L2 is mostly implicit. That, however, does not settle the question of whether, before native-like fluency in L2 is reached, there is a need for explicit instruction.

There are two positions concerning the question, 'how fluent can a speaker become without explicit knowledge?'. They are the Noninterface Position, which argues that implicit knowledge is not influenced by explicit knowledge, and the Interface position, which urges that the acquisition of implicit knowledge may be influenced by explicit knowledge. The Interface Position is divided into a Strong-Interface Position and a Weak-Interface Position. According to the Strong Position, explicit knowledge becomes implicit knowledge through practice. This position is derived from skill acquisition theory; L2 acquisition is seen as the automatization of the application of explicit grammar rules. According to the Weak Position, explicit knowledge only aids the acquisition of implicit knowledge. If a learner is ready for the new knowledge, his conscious knowledge will become implicit. Application of implicitly knowledge can merely be improved through explicit instruction (Ellis, 1993).

Let us now turn to philosophical definition(s) of consciousness.

Consciousness in Philosophy

The initial task of this paper was to consider what philosophers have to say about consciousness in order to search for conceptual issues that may ease and perhaps resolve the current debate in SLA related to the role of consciousness in L2 learning and/or acquisition. Let us return to the issue of what philosophers have to say about consciousness.

Block (1999) introduced an interesting categorization of consciousness into A-consciousness and phenomenal P-consciousness. Block argues that A-consciousness is informational processing and control of thought and action. According to him "a state is A-conscious if it is poised for direct control of thought and action, .. for free use in reasoning and for direct 'rational' control of action and speech." (Block, 1999). By contrast, he defines P-consciousness as what we see, smell, taste, and feel. According to Block, P-consciousness is what it is like to have sensations, feelings, perceptions, thoughts, wants, and emotions: "what makes a state phenomenally conscious is that there is something it is like to be in that state" (Block, 1999). P-consciousness is what we ordinarily call experience.

Block points out that there are three main differences between A-consciousness and P-consciousness. The first difference concerns content. P-consciousness content is phenomenal (it is like something to have it) while the content

of A-consciousness is representational. The latter enters into reasoning, behavioural control, etc. The second difference is that A-consciousness is defined in terms of functions in a cognitive system while P-consciousness is not. The third difference is in the paradigms of each type of consciousness. The paradigmatic cases of P-consciousness are sensations, while those of A-consciousness are propositional attitudes.

As for the relationship between A-consciousness and P-consciousness, Block argues that even though A-consciousness and P-consciousness are separate entities, they do interact, influence one another and might even be the product of one another. A P-consciousness change in what is figure and what is ground, for example, might have functional effects on what one comes to believe or do. However, lack of one type of consciousness does not guarantee lack of the other. We will return to the issue of whether it is possible to have A-consciousness without P-consciousness or vice-versa.

Let us now examine how L2 acquisition and language in general fit into the Block's distinction.

Philosophical Views of Consciousness and the Issue of Conscious Instruction

So far we have laid out the controversy in SLA on the question of whether L2 learners benefit from direct grammar instruction and we had looked at a philosophical view of consciousness. Let us now try to connect the two. The hope is that philosophy can help us to ease this controversy. How does L2 acquisition fit into the distinction between A-consciousness and P-consciousness?

A-consciousness plays an important role in reasoning and information processing. It is closely related to 'knowing how to do something'. P-consciousness, by contrast, is 'it being like something to be in some state'. And, as we saw, however, different these two notions are, the two kinds of consciousness interact. In particular, one can be P-conscious of knowing how to do something. Similarly, the way something feels to you can make a difference to cognitive functioning. What we now need to consider is how the two types of consciousness relate to our knowledge of language, in particular our knowledge of the syntactic structure of the language.

Let us introduce Chomsky's distinction between competence and performance. Competence refers to a speaker's knowledge of the language while performance is the actual use of language and reflects not only competence but also such other factors as ability to utilize competence, time constraints, and so on. Performance is the actual use of language in different situations, how we actually speak, use, or manipulate language. Linguistic performance is part of a lot of A-consciousness. Competence, 'speaker's/hearer's knowledge of language', is not tied in the same way to P-consciousness. Most of our competence is in this sense

unconscious. Still, there is a relationship between competence and P-consciousness, as we will see. To bring out this relationship, let us connect A-consciousness and P-consciousness to implicit and explicit knowledge. We will argue that P-consciousness is similar, if not identical, to explicit knowledge and that explicit instruction which eases the acquisition of implicit knowledge enhances competence.

Start with UG. If UG is innate, it is not dependent on P-consciousness. What is developed after the triggering effect of the language environment is at least A-consciousness, 'poised for control of thought and action'. A-consciousness of language is not present at birth. A-consciousness of language is indirectly influenced by P-consciousness of language with which it interacts even during the developmental phase because children not only come to use language, it is like something for them to have language (in the usual, P-conscious sense of the term, they are conscious of the language they know), and this consciousness has effects on how they use language. The two types of consciousness of language develop roughly simultaneously. However, that does not show yet that P-consciousness of language enhances any of acquisition, competence, or performance.

Time to bring L2 acquisition back onto the stage. Does P-consciousness have a special role to play in it? We think it does. The Partial Access Hypothesis introduced earlier in this paper shows why. If an L2 learner needs to learn all the parameters of UG that are not common to his L1 and L2, that means that the parameters peculiar to his L2 are not included in his current linguistic competence. If all UG parameters are present at birth, then the UG parameters peculiar to the L2 were lost at some point during or after the process of L1 acquisition. These missing parameters is a major difference between L1 and L2 acquisition. Put in terms of the language of consciousness, the parameters that have dropped out are in neither the subject's A-consciousness or P-consciousness of language. (An implication of this is that, not surprisingly, consciousness of language is language specific.)

We should agree with Krashen when he points out that there are two different processes in L2 development, namely learning and acquisition. However, it does not follow that acquisition is fostered by avoiding explicit instruction. Recall that in L2 learning, both implicit and explicit knowledge are present. It is plausible to suggest that if a required piece of linguistic competence is no longer part of the current competence of a learner, then he will need to learn it explicitly in order to (re)gain an implicit, automatized ability to use it again.

Earlier in this paper Ellis' definition of explicit and implicit knowledge with regard to L2 learners was accepted. However, the definition of the two types of knowledge needs to be modified in terms of P-consciousness and A-consciousness of language. Explicit knowledge is something that a learner is P-conscious of and can verbalize on request. By contrast, though

some implicit knowledge is A-conscious, it is by definition never P-conscious. Even though we are not P-conscious of our implicit knowledge, the latter can be influenced by explicit, P-conscious knowledge, just because A-consciousness can be influenced by P-consciousness.

Now that we have presented arguments that linguistic performance consists (at least often, maybe always) in A-consciousness of language and P-consciousness of language can enhance implicit, A-conscious competence and performance, let us now look at their interaction in a bit more detail, to try to see where explicit instruction fits.

We presented the Interface Positions earlier in this paper and said that according to the Weak Position explicit instruction in L2 directly influences explicit knowledge which aids the acquisition of implicit knowledge. Given the connection between A-consciousness of language and implicit knowledge and P-consciousness and explicit knowledge, the Weak Position and Block's (1999) view that P-consciousness can influence A-consciousness are in line with one another.

In L1 acquisition, there is no need for direct instruction. During this process implicit knowledge of language, including A-consciousness of it and P-consciousness or explicit knowledge of language are present. On the one hand, native speakers can always judge whether or not a sentence is grammatically acceptable. However, in most cases they cannot explain why. They have explicit knowledge of the sentence's grammaticality, only implicit knowledge of why. In the case of L2 learners, the situation is quite the opposite. If they can judge the grammaticality of a sentence, they can also cite the relevant rules. Implicit knowledge of rules plays little role since the necessary competence is not innate and yet the acquisition process has not yet rendered it automatic and implicit. Indeed, it is not rare that an L2 learner is capable of explicitly spelling out a grammatical rule of his L2 and yet cannot apply it in his spoken or written L2 productions. To sum up, explicit grammar instruction, essential for acquisition of explicit knowledge (P-consciousness), can also enhance implicit linguistic competence and performance. For that reason, it should be used in L2 teaching (see Figure 1).

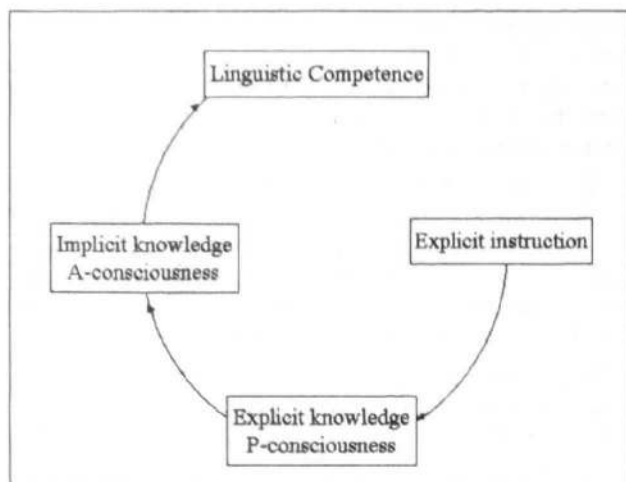

Figure 1: Indirect effect of explicit instruction in L2 on linguistic competence

Conclusion

In this paper we examined an important question for SLA theory, namely, the role of consciousness in L2 acquisition. This question was examined in order to determine whether or not explicit instruction in grammar is advantageous during this process.

We first compared the definitions of consciousness accepted in the two disciplines and concluded that perhaps SLA theorists need to consider consciousness in a broader sense than they do.

We next looked at how different SLA theories view the role of consciousness and we examined the controversy in SLA theory concerning the value of explicit instruction in grammar. In this connection, we paid special attention to the role of UG in L2 acquisition and role of implicit and explicit knowledge in use of UG.

This led us to Block's distinction between A-consciousness and P-consciousness. We examined how L2 acquisition and language in general fit this categorization. We suggested the following:

- linguistic performance is a form of A-consciousness, often at least,
- subjects can be both A-conscious and P-conscious of language, including UG,
- A-consciousness of language can be language specific,
- A-consciousness of language is a form of implicit knowledge, while P-consciousness of language is explicit knowledge,
- P-consciousness can influence A-consciousness, and,

- P-consciousness of language can enhance linguistic competence by improving implicit knowledge.

The relationship of all this to explicit instruction in L2 teaching is as follows. Explicit instruction influences explicit knowledge, obviously. Having explicit knowledge means being P-conscious. But having explicit knowledge or P-consciousness of language can influence one's A-consciousness of it. In this way, P-consciousness can enhance L2 competence and implicit knowledge (see figure 1).

This paper tries to provide a theoretical base for the value of explicit grammar instruction in L2 training. What needs to be examined next is the form of the instruction. One of us has pointed out elsewhere that instruction in grammar should take the form of task-based, form-focussed instruction that contains both positive and negative evidence (Torlaković, 2001).

Abstract

This study investigates the strategies used by expert scientists to evaluate hypotheses when they analyze data. We used an *in vivo* methodology to observe experts' on-line thinking. In contrast to the results of laboratory studies of scientific reasoning, we found that the scientists rarely used experimentation but relied on a variety of other strategies, including conceptual simulation. This strategy was most prevalent in evaluating a hypothesis about a phenomenon that violated the scientists' expectations.

Introduction

How do scientists test and evaluate hypotheses? One obvious answer is that they design and conduct experiments. The canonical method of scientific inquiry is represented by a cycle of hypothesis generation, experimentation, data analysis and hypothesis refinement that has its roots in the philosophy of science (Popper, 1956) and is frequently taught explicitly to students (Okada & Shimokido, 2001).

Psychologists investigating the processes of scientific reasoning have also been influenced by the "scientific method" and so have focused on experimentation in investigating hypothesis-evaluation strategies. There have been numerous laboratory studies of scientific reasoning in which participants are asked to find the cause of a given effect (e.g. Dunbar, 1993; Schunn & Anderson, 1999), or to identify the role of a causal mechanism (e.g., Klahr & Dunbar, 1988; Trafton & Trickett, 2001a; Trickett, Trafton, & Raymond, 1998; Vollmeyer, Burns, & Holyoak, 1996). In these studies, participants propose hypotheses, then design and run experiments to test them.

There are several reasons why participants in laboratory studies of science use experimentation to evaluate hypotheses. The instructions in these studies explicitly tell participants to run experiments. Participants have little choice—they are provided with limited time, equipment, and materials. Moreover, they are frequently asked to reason in a domain about which they have no relevant knowledge. Running an experiment is also "cheap"—the variables are already identified, it involves a few mouse-clicks, and the results are almost instantaneous and easy to interpret.

However, practicing scientists have a wider array of options. They can select their own methods and equipment, and, as experts, they have domain knowledge to guide their problem-solving. Experimentation may *not* be the best strategy, as it is expensive in terms of planning, paperwork, personnel, the need for special equipment, the complexity of data interpretation, and the high cost of errors.

What strategies besides experimentation might scientists use to evaluate hypotheses? Prior research on scientific thinking suggests several possibilities. One likely strategy is extracting information from data, whether by reading off information, transforming data, replottting data), or looking at data that is not currently on view but that is available. Trafton found that expert meteorologists spent considerable time on information extraction (Trafton et al., 2000).

Given the cost of experimentation, it is also likely that scientists use different strategies to reason about hypotheses before committing to an experiment. Analogical reasoning has been shown to be a powerful strategy in science (Clement, 1988; Dunbar, 1997; Gentner et al., 1997). It allows people to make inferences about an unknown entity based upon their knowledge of a different, known entity (Gentner, 1983) and has been proposed as a mechanism of conceptual change in numerous historic scientific advances (Gentner et al., 1997; Nersessian, 1992; Thagard, 1992). It is also a strategy used by successful contemporary scientists in scientific problem-solving, such as hypothesis generation (Clement, 1988), experimental design (Dunbar, 1997), and discovery itself (Ueda, 1997). Given its widespread use in other aspects of scientific reasoning, it seems plausible that analogy may be used as a hypothesis-testing strategy; however, whether this is the case remains an open question.

Conceptual simulation has also been shown to be a means of successful scientific reasoning (Nersessian, 1999; Qin & Simon, 1990; Schraagen, 1993). A conceptual simulation is a mentally constructed model of a phenomenon or data representation that is manipulated in such a way that there is a resulting change of state (a formal definition is provided below). As with analogy, conceptual simulations have been proposed as a strategy used by both historical and practicing scientists. In historical reconstructions, Ippolito and Tweney have developed a model of insight that involves the construction of a dynamic, "runnable" mental model (Ippolito & Tweney, 1995), and Nersessian proposes that scientists construct and conduct mental experiments that yield usable data, in a process that mirrors an empirical experiment (Nersessian, 1999). In contemporary scientific problem-solving, Hegarty has found that people develop sequences of mental animations (Hegarty, 1992). Qin and Simon (1990) found that people used a series of mental processes of manipulation, control, and inspection in order to extract information that was only implicit in their initial mental image. Similarly, participants in Schraagen's study of experimental design used a strategy of mental simulation to project what experimental procedures would look like under particular circumstances (Schraagen, 1993). As with

analogy, how much scientists use conceptual simulations in evaluating hypotheses remains an open question.

One can imagine several other means whereby scientists might evaluate a hypothesis. For example, a scientist might consult a colleague or other expert or attempt to tie the hypothesis into current theoretical understanding of the domain. A scientist might also defer evaluation until some later time or even abandon a hypothesis altogether.

The purpose of this research is to investigate the means by which scientists evaluate hypotheses. In order to investigate this issue, we adapted Dunbar's *in vivo* methodology (Dunbar, 1997), an observational technique developed to study creative and complex thinking in a real-world context. The main advantage of Dunbar's method is that it allows the collection of on-line measures of thinking by experts engaged in authentic scientific tasks.

Method

We chose to investigate scientists at work during the data analysis phase of their research because it is a stage at which a great deal of scientific reasoning takes place. Scientists must integrate their expectations about the data with the actual data; it is thus likely to be rich in hypotheses.

We analyzed 8 different datasets from 9 scientists working in one of 4 domains—neuroscience, astronomy, computational fluid dynamics (CFD), and psychology. Each dataset consists of a recorded session in which one or more scientists analyzed their data.

Participants were all working scientists recruited through personal connection of the experimenters. Either they were expert scientists who had earned their PhDs more than 6 years previously, or they were graduate students working alongside one of these experts. Only experts with a Ph.D. worked alone; in the group sessions involving graduate students, the scientist in charge always had a Ph.D.

Participants agreed to contact a member of the research team when they were ready to conduct some analysis of recently acquired data, and an experimenter visited the scientists at their regular work location. Participants working alone were trained to give talk-aloud verbal protocols. For scientists working in groups, we recorded their conversation as they engaged in scientific discussion about their data. All participants were instructed to carry out their work without explanation to the experimenter (Ericsson & Simon, 1993). It is important to emphasize that all participants were performing their usual tasks in the manner in which they typically did so. At the beginning of the session, some participants gave the experimenter an explanatory overview of the data and the questions to be resolved, and after the session, the experimenter interviewed the participants to gain clarification about any uncertainties. During the analysis session itself, however, the experimenter did not interrupt the participants.

All utterances were later transcribed and segmented according to complete thought. All segments were coded by 2 coders as on-task (data analysis) or off-task (e.g., software management, phone interruptions, jokes, etc.). Inter-rater reliability for this coding was more than 95%. Introductory

comments from the scientists to the experimenter and post-session interviews of the scientists were excluded from analysis. The number and percentage of on-task utterances, the number of participating scientists, and the duration of the relevant portion of each individual session are reported in Table 1. Finally, a coding scheme (described below) was developed to examine how the scientists evaluated hypotheses they developed in the course of analyzing data.

Table 1: Characteristics of datasets

Domain	Utterances:		Time (mins)	# scientists
	On-Task	Total		
Astronomy	649	859	49	2
CFD sub	430	954	39	1
CFD laser 1	172	400	15	1
CFD laser 2	184	249	13	1
fMRI	317	373	55	2
Neuroscience	219	343	54	2
Psychology 1	482	541	31	3
Psychology 2	914	1426	75	2

Although each scientist or group used different tools, their tasks shared several characteristics. All the scientists were analyzing data that they themselves had collected, from observations, from a controlled experiment, or from running a computational model. They displayed this data using their regular tools, whether custom-built visualization programs, while others used widely available commercial products, such as Microsoft's Excel. Figure 1 shows an example of the type of data examined by the astronomers. Visualizations used in other domains were similarly complex.

Figure 1: Example of data examined by astronomers. Radio data (contour lines) are laid over optical data.

Almost all sessions represented the initial investigation of this data (the exception was the second CFD session, which was a follow-up to the first session). Although in some sessions the scientists did not have strong *a priori* beliefs about the data (these sessions were thus exploratory), in others, the scientists did approach the task with particular hypotheses that they expected to be supported by the data. It is interesting to note, however, that none of the scientists performed any statistical analyses

Coding Scheme

In addition to coding all segments as on- or off-task, we coded the following (see Table 2 for examples):

Table 2: Examples of coding scheme
(Coded utterance in italics)

Code	Utterance
Hypothesis	You'd think [the number of reclassifications] would go up for condition C, but it didn't... <i>So maybe the subjects are having a better memory of the ones they've already done</i> (Psychology 2)
Data collection	<i>Do you think it's worth getting some more time, just to do an offset plane, or offset velocity?</i> (Astronomy)
Information extraction	<i>Well, that's a really clean neuron,, uh it goes down and up and away from the edges</i> (Neuroscience)
Consult colleague	<i>I'm gonna have to discuss it with ah, Robbie when he gets back.</i> (CFD submarine)
Tie-in with theory	<i>OK, so how do these Fourier modes work?</i> (CFD laser 1)
Analogy (general)	<i>Think of this as a spiral arm</i> (Astronomy)
Analogy (alignment)	And, if I've got a scaling problem, then it should show up here too, <i>but it doesn't show up here</i> (CFD submarine)
Conceptual simulation	<i>In a perfect sort of spider diagram, if you looked at the velocity contours without any sort of streaming motions, no, what I'm trying to say is, um, in the absence of streaming motions, you'd probably expect these lines here to go all the way across, you know, the ring</i> (Astronomy)

Hypotheses All statements that attempted to explain or account for a phenomenon identified in the data were coded as hypotheses. After a hypothesis, utterances that pertain to (elaborate) that hypothesis were identified. Such utterances constitute further investigation of the hypothesis and may be support or oppose the hypothesis. All subsequent utterances pertaining to a hypothesis were coded as follows:

Data collection Utterances in which the scientist proposed to collect more data were coded as data collection strategies. These include statements that propose an experiment, plans

to run such an experiment, or plans to collect additional data for an experiment that has already been run (e.g., increasing the sample size or making some other adjustment) or to collect more observational data. Data collection strategies also include plans to build and run computational models.

Information extraction Statements that "read off" data from the visible display (i.e., extract information) were coded as information extraction (Trafton et al, in press). In addition, we coded as information extraction strategies statements that refer to looking at data in a different way (e.g., replotted the data or displaying it in a different visualization), to "tweaking" data (by transformation, removing outliers, etc.), or to looking at data that is not currently on view but that is available.

Consult a colleague Utterances that refer to showing the data to or asking the opinion of a co-worker or other expert were coded as consulting a colleague.

Tie-in with theory We expected that expert scientists with a vast array of domain knowledge stored in memory were likely to apply that theoretical domain knowledge to their hypotheses. We coded as "tie-in with theory" utterances that refer to theoretical underpinnings of the data.

Analogy/Alignment Although different theories of analogy specify different processes by which the mapping between source and target occurs (Gentner, 1983; Holyoak, 1985), all theories share these elements: source, target, and a process of mapping or alignment. During alignment, the relevant parts of the source are "applied" to the target. It is thus during this phase that inferencing occurs, and hence we expected that scientific reasoning would occur during this part of the analogical process.

We coded analogies using the definition and coding scheme developed by Dunbar (1997). According to this scheme, analogy is coded when a scientist either refers to another base of knowledge to explain a concept or uses another base of knowledge to modify a concept. Analogies were coded at both a "general" level (e.g., "The atom is like the solar system") and at the level of the actual mapping or alignment. Statements of similarity (i.e., "X is like Y") were not considered analogies; they do not provide explanations nor result in mapping features from the source to the target.

Conceptual Simulations Recall that a conceptual simulation is a mentally constructed model of a phenomenon or data representation. The initial representation may be grounded in memory (e.g., theoretical knowledge of the phenomenon) or in a mental modification of the displayed image. The key feature of a conceptual simulation is that it involves a simulation "run" that alters the representation, such that there is a change of state.

To code conceptual simulations, we adapted Trafton's spatial transformation framework (Trafton & Trickett, 2001b; Trafton, Trickett, & Mintz, in press;). We conducted

a spatial transformation analysis to determine for each on-task utterance whether the speaker was extracting information from the display ("read-off") and which mental operations, if any, were applied to a representation. Some possibilities include rotation, modification, moving an image, creating a mental representation, animating features, and comparison. Conceptual simulations may be defined formally as a specific sequence of spatial transformations:

1. Create representation: The scientist creates a mental representation that is not the same as the currently displayed representation. This representation creation may occur via the display (it modifies the display), via theory, (a theoretical construct); or via memory (the scientist recalls a previously viewed representation).
2. Simulation Run: The scientist builds on the created representation by spatial transformation (e.g., extend, add, delete) such that its state is changed.

Note that these codes are not mutually exclusive, and that the created representation and explicit run can occur in the same utterance. Approximately 20% of the data has been coded for conceptual simulations by 2 independent coders, and initial inter-rater reliability was greater than 90%.

Results

Eight *in vivo* datasets, comprising 330 minutes of relevant protocol and 3508 on-task utterances were analyzed. We coded 68 hypotheses, an average of approximately 1 hypothesis every 5 minutes. 57 hypotheses (84%) were elaborated; that is, the scientist made some follow-up utterance(s) that further explored the hypothesis.

How did the scientists evaluate the hypotheses?

We identified and counted the type of utterance following each hypothesis. Table 3 summarizes this count. Counts were performed in the following manner: Each individual instance of information extraction was included in the count. For example, the sequence "If I look at the average of that, it's a nice clean spike" (utterance 1) "and I can look at the standard deviation around that and it's pretty tight right in the middle where it needs to be" (utterance 2) was coded as two instances of information extraction. Each utterance identifies a different piece of information extracted (average, standard deviation). In all other cases, the count was based on the number of instances of the coded phenomenon. For example, the sequence "In a perfect sort of spider diagram" (utterance 1) "if you looked at the velocity contours without any sort of streaming motions, (utterance 2) "no, what I'm trying to say is, um, in the absence of streaming motions," (utterance 3) "you probably would expect these lines here [gestures] to go straight across, you know, the ring" (utterance 4) was coded as one conceptual simulation because each utterance contributed to, but did not constitute, one conceptual simulation.

As Table 3 shows, the most frequent strategy used for evaluating hypotheses was information extraction. This result is unsurprising, in that the scientists' task was to examine and analyze the data; one would therefore expect

them to devote a significant amount of time to extracting information directly from the data itself. Similarly, the second most frequent strategy, tie-in with theory, might also be predicted from an understanding of the general procedures of science. These scientists have significant expertise and knowledge of the theories relevant to their domains, and one would expect them to consider new data in the context of current theoretical understanding of the domain. One might also expect data collection strategies (which include plans to design or conduct experiments) to occur frequently; however, these were one of the *least* frequent strategies used by these scientists.

Table 3: Frequency of hypothesis-evaluation strategies

Strategy	Frequency
Information extraction	268
Tie-in with theory	36
Conceptual simulation	34
Analogy/Alignment	30
Data collection	3
Consult a colleague	1

The use of analogy is also of interest. Of the 30 uses of the analogy/alignment strategy, only one consisted of a "general" analogy. The remaining 29 were alignments in which the mapping between source and target actually took place. This result is consistent with findings of other studies in which analogy use has been found to be more "local" than "global" (Dunbar, 1997; Saner & Schunn, 1999). The use of alignment is discussed in more detail below.

Of particular interest is the relative frequency of the conceptual simulation strategy. Specifically, this strategy was linked with the alignment strategy in a sequence that took the form of conceptual simulation followed by alignment. There were 34 conceptual simulations and 29 alignments; out of these, there were 27 Conceptual Simulation → Alignment sequences. Thus most (79%) of the conceptual simulations were immediately followed by an alignment, and most (93%) of the alignments immediately followed a conceptual simulation.

The frequency of the Conceptual Simulation → Alignment sequence suggests a tight coupling between the two strategies. It appears that the scientists used conceptual simulation to build a "mental model" of the data, based on assumption that the hypothesis under evaluation was true. The scientists used the data on display and their domain knowledge to investigate the implications of the hypothesis, by dynamically constructing a mental simulation of a series of processes. The result of this conceptual simulation was an inspectable mental model that was used as the source of comparison with the actual data in the alignment process. To the extent that the two models aligned, the hypothesis was supported; if there were relevant differences between the models, the hypothesis would be rejected. Figure 2 illustrates this process of model-building and alignment.

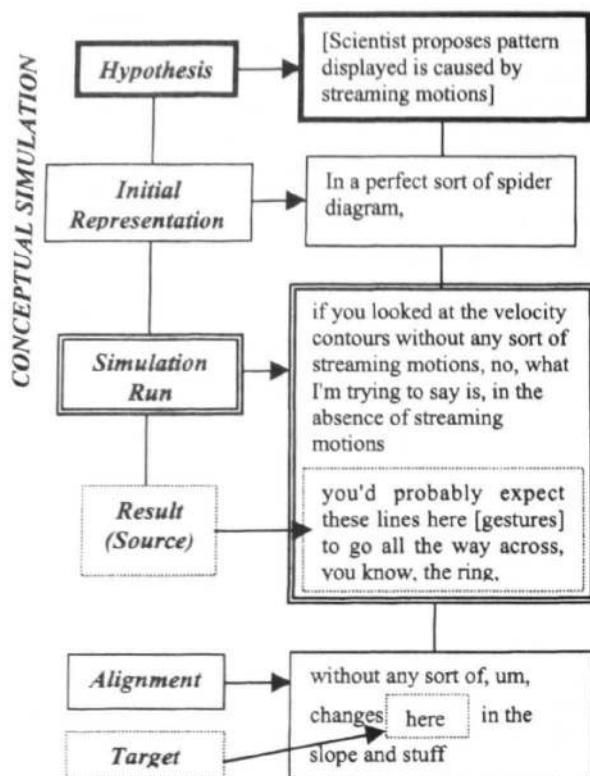

Figure 2: Conceptual simulation as source of comparison in alignment process

Why were conceptual simulations used?

There were 57 elaborated hypotheses in these datasets, and 34 conceptual simulations. The high frequency with which conceptual simulation was used as an evaluation strategy indicates that its use is important and significant. Under what circumstances did the scientists use this strategy? Conceptual simulations were used across a variety of criteria: in both group and individual settings, when the data consisted of either images or numerical tables, in exploratory and confirmatory analysis sessions, and across a variety of domains. It seems, therefore, less likely that conceptual simulations were motivated by characteristics of the data than by some characteristic of the task.

An examination of the structure of a conceptual simulation reveals that its dynamic nature allows an understanding of the *processes* involved in constructing the revised mental representation of the relevant phenomenon. Understanding process may be particularly important when there is significant uncertainty. For example, a poorly understood phenomenon is likely to evoke more investigation than one that is well understood (Trickett, Trafton, & Schunn, 2000). Thus we conjectured that the use of conceptual simulation, with its associated construction of underlying process, was associated with attempts to account for a phenomenon that violated the scientists' expectations.

In order to investigate this possibility, the hypotheses in this dataset were categorized into those that attempted to account for some expectation that wasn't met, and those that

pertained to some expected phenomenon. The coding criteria for this categorization were adapted from Trickett et al., 2000. In some cases, the scientists made explicit verbal reference to the fact that something was expected or unexpected. If there was no explicit reference, domain knowledge was used to determine whether a phenomenon was expected or not. A phenomenon might be associated with (i.e., identified as similar or dissimilar to) another phenomenon that had already been established as expected or not, or the scientist might question a phenomenon, thus implying that it was not what was expected. This coding scheme was applied by two independent coders to a subset of the data (the entire astronomy protocol), and agreement between those coders was 87%. Table 4 provides examples.

Table 4: Examples of expectation-violation hypotheses (hypotheses in italics)

Domain	Utterance
CFD (submarine)	Computational model does not agree with the experiments in the least... <i>It could be that the turbulence is all screwed up too.</i>
Astronomy	That, that's odd...Why isn't there star formation going on there?... <i>It may be because of the large velocity dispersion.</i>

After we coded the hypotheses as associated with expectation violation or confirmation, we counted the use of conceptual simulation and information extraction strategies to evaluate each type of hypothesis. Note that the purpose of the analysis was to determine the circumstances under which each strategy was used, not the frequency with which the strategy followed a hypothesis; thus, only the first instance of each strategy use was counted. We performed a *phi* coefficient association measure. The correlation between hypothesis type and conceptual simulation was significant, $r_{\phi} = .487$, $p < .01$. There was no correlation between hypothesis type and information extraction, $r = .006$. Table 5 summarizes the results of this analysis.

Table 5: Strategy use and hypothesis type

	Violate Expectation	Confirm Expectation
Conceptual Simulation	22	3
Information Extraction	27	20

General Discussion and Conclusion

The protocol data discussed above have provided a rich dataset by which to investigate the on-line thinking of working scientists analyzing data. The scientists develop hypotheses to account for the data and then evaluate those hypotheses in light of theoretical knowledge and the data itself. In contrast to results of laboratory studies of scientific reasoning, the analyses presented above reveal that the scientists *rarely* chose to evaluate hypotheses by

experimentation (including planning experiments). They frequently used a strategy of conceptual simulation followed by alignment. In particular, they used the conceptual simulation-alignment strategy most often to evaluate a hypothesis about something that violated their expectations.

Conceptual simulation is a process of mental model-building and manipulation that results in a revised mental model, or "Qualitative Mental Model" (QMM) (Trafton et al., 2000). This QMM serves as the source of an analogy that allowed the scientists to compare the QMM with the observed data and from there to evaluate the scientist's current hypothesis. Insofar as the QMM matched the data, the scientist found evidence for the hypothesis; in the absence of a match, the scientist needed to revise the hypothesis. The alignment between source (QMM) and target (data) occurred as a series of mental processes, which amount to a recreation of the *processes* that underlie the external manifestation of the phenomenon of interest.

Abstract

Fourteen statistics novices were asked to solve three statistics word problems under standard (SGS) or reduced (RGS) goal specificity. Later, they were asked to solve both structurally identical and structurally different transfer problems, and their structural knowledge of the domain was assessed. Results indicate that participants in the RGS condition performed better on the structurally different transfer problems and had acquired structural knowledge more similar to that of a domain expert. These results extend previous work in showing that the schematic knowledge acquired under reduced goal specificity training is more general than previously realized. The goal specificity effect is discussed in terms of the attentional focus required to solve RGS and SGS problems.

Introduction

Most theorists agree that schemas form the basis for problem solving expertise. Schemas are typically described as knowledge structures that represent generalized concepts, and are comprised of facts and procedures as well as the interrelationships among those facts and procedures. With respect to problem solving, it is generally accepted that schemas allow: (1) problems to be classified according to the general principles required for their solution (Chi, Feltovich, & Glaser, 1981), (2) solution planning (Priest, & Lindsay, 1992), and (3) use of forward-chained solutions (Koedinger, & Anderson, 1990), all of which are hallmarks of expertise. Thus, an important issue for cognitive scientists and educators alike is to understand how schemas are learned.

Cognitive Load Theory (CLT) has been advanced to describe the relationship between problem solving and learning (Sweller, & Levine, 1982; Sweller, 1988). CLT posits that acquisition of schematic knowledge during problem solving is not automatic; rather, it requires a certain amount of cognitive resources. Therefore, if a problem solving task or strategy demands a great deal of cognitive resources then learning will be impaired relative to a task or strategy that carries a low cognitive load.

CLT has been used to explain the finding that reducing the specificity of goals enhances problem solving performance, otherwise known as the goal specificity effect. The goal specificity effect has been shown in maze learning (Sweller, & Levine, 1982), kinematics (Sweller, Mawer, & Ward, 1983), geometry (Ayres, 1993; Sweller, Mawer, &

Ward, 1983), trigonometry (Owen, & Sweller, 1985; Sweller, 1988), and several more complex, dynamic tasks (Miller, Lehman, & Koedinger, 1999; Vollmeyer, Burns, & Holyoak, 1996). According to CLT, problems with standard goal specificity (SGS), in which problem solvers are given values for several variables and asked to solve for the value of a specific unknown variable, encourages use of a means-ends strategy. Under a means-ends strategy, problem solvers' attention is focused on reducing the difference between the current problem state and the goal. Moves are guided by the goal state, which requires solvers to keep in memory the goal, any subgoals, and the current problem state. Because this task is cognitively demanding, it detracts from the learning of relations that are relevant for schema acquisition. Reduced goal specificity (RGS) problems, in which problem solvers are asked to solve for the value of as many unknown variables as possible rather than the value of a *specific* unknown variable, eliminate the possibility of a means-ends strategy. Instead, they require a forward-working strategy where moves are generated solely by the current problem state. Because this strategy is less cognitively demanding (see Sweller, 1988), resources are available for learning the relations relevant to schema acquisition, namely, relations between the appropriate operators and problem states.

According to CLT, training with RGS problems is more likely to lead to schema acquisition than training with SGS problems, where schemas are defined as knowledge of problem states and their associated operators. However, this definition of a schema is limited in that it is only applicable to problems with similar structure as those encountered during training (i.e., problems that share, at least some of, the same problem states as the training problems). We will call this the *limited schema view*. Actually, it is difficult to distinguish this view from one that simply postulates the storage of exemplar solutions. If one remembers previous problem solutions, they then have knowledge of problem states and their associated moves/operators...the same information contained in limited schemas. Under this *exemplar view*, the goal specificity effect can be explained by the notion that RGS solutions are easier to remember than SGS solutions (since they require less cognitive load to perform, more resources are available to store them), and they are forward-working. A third alternative is that schemas are acquired under RGS training and that they are

more general than previously believed. We will refer to this possibility as the *general schema view*.

Most of the previous studies investigating the goal specificity effect cannot distinguish among these views, because they have predominantly looked at transfer performance on problems that were structural identical to training problems. For example, Sweller, et al. (1983) showed that novices who practiced with RGS kinematics and geometry problems were more likely to work forward on structurally identical test problems than those who practiced with SGS problems. Although consistent with the idea that RGS participants had acquired schemas (either limited or more general), this result is also compatible with the exemplar view. Since novices tend to use means-ends analysis on standard problems, the solutions to SGS practice problems will be backward-chained, whereas since RGS problems eliminate the possibility of using a means-ends strategy, the solutions to RGS practice problems will be forward-chained. Applying these stored exemplar solutions to test problems would result in forward solutions for RGS participants and backward solutions for SGS participants. Schematic knowledge is not required to account for this finding.

If we assume that the greater cognitive load associated with SGS problems interferes with storage of exemplar solutions, then an exemplar view can also account for the findings that SGS training leads to more errors on isomorphic transfer test problems (Owen, & Sweller, 1985), fewer practice problems accurately recalled (Sweller, 1988), and other related findings.

Furthermore, none of the results mentioned above can distinguish between the limited and general schema views, because both limited and general schemas would apply equally well to problems that are structurally the same as the problems from which the schemas were generated. Structurally different transfer problems, though, would help make the distinction. Limited schemas, comprised of relations between previously encountered problem states and associated operators, would not apply to structurally different problems that have different problem states and different solutions. Exemplar solutions of training problems would not apply either. General schemas that are based on abstract principles, though, would apply to structurally different problems, so long as they could be solved with the same general principle. One finding that may favor the general schema view comes from Owen and Sweller (1985). They trained participants to solve trigonometry problems under either SGS or RGS conditions. Training problems gave values for one side and one angle in a right triangle, and participants were asked to solve for either a specific side of an adjacent triangle, or to solve for the values of as many sides as possible, using the trigonometric ratios sine, cosine, and tangent. Later, performance was tested on structurally identical transfer problems, for which RGS participants showed an advantage. They also tested performance on a diagram construction task in which participants were given values for two sides of a right

triangle and were asked to draw the triangle, labeling the values for all three sides. Due to the fact that RGS participants fared better on this diagram construction task as well, the authors concluded that mathematical schema acquisition involves learning mathematical principles, where mathematical principles seem more akin to general than limited schemas. Unfortunately, Owen and Sweller (1985) did not control for the number of sides solved for during training. Because the RGS condition tended to solve significantly more sides during training, any differences upon testing could be attributed to amount of practice rather than goal specificity per se. In the present study, we will use transfer problems that are structurally different from training problems, while also controlling for amount of practice.

Another issue with CLT that remains largely untested is the description of the processes used to account for the effect of goal specificity on schema acquisition. Although Sweller (1988) constructed computational models of SGS and RGS problem solving to show that solving SGS problems do indeed require more cognitive resources, it is nonetheless possible that the functional difference between SGS and RGS problems is solely where attention is focused when solving such problems, and does not depend on the amount of resources available to encode problem information during that time. That is, SGS training might produce just as much learning as RGS training, but if attention is focused in the wrong places, then SGS training will result in erroneous learning. In order to examine this idea, we will employ a structural knowledge measure that is measured independent of problem solving performance, and that allows relatively specific questions about the process of schema acquisition to be tested.

Structural knowledge refers to knowledge of the interrelationships among domain concepts, and is well correlated with domain expertise (for a review, see Goldsmith, Johnson, & Acton, 1991). As such, it is likely to be at least a subset of the knowledge contained in schemas. Trumpower (2000) has shown how network representations of structural knowledge can be used to assess schema acquisition. Briefly, the process involves comparing participants' knowledge networks with those of domain experts. Figure 1 displays a knowledge network of the statistics concepts used in the present study, derived from two statistics experts.

Figure 1: Expert knowledge network

According to an attentional focus explanation of the goal specificity effect, RGS training allows learning of the relationships between problem states (i.e., the subset of

variables that are known at a given time) and appropriate operators (i.e., the equation that can be used at that same time to solve for an unknown). Thus, we might predict that RGS training will result in learning of the relations among concepts contained in the equations used to solve RGS problems, since the equations are the operators and contain the currently known variables. By inspecting the three equations needed to solve training problems in the current study (listed below in the Problem Domain & Materials section), we see that relations among concepts in those equations correspond almost perfectly with the pattern of links in the expert network shown above. Therefore, we predict that participants undergoing RGS training will acquire knowledge structures that look very similar to the expert network shown above.

For SGS training, an attentional focus explanation says that attention is directed toward the goal and reducing differences between current states and the goal, at the expense of noticing the local relationships described above. Therefore, we predict that SGS training will result in making associations between all problem states or known variables and the goal (e.g., links between a - SS_B , df_B - SS_B , MS_B - SS_B , MS_W - SS_B , F - SS_B), but a failure to notice the relevant relations between non-goal concepts (e.g., links between a - df_B , df_B - MS_B , F - MS_B , F - MS_W).

To summarize, the current study addresses three questions: (1) Does goal specificity have its effects primarily on storage of exemplar solutions or schema acquisition?, (2) If the effects are on schema acquisition, then how general are the acquired schemas?, and (3) Can the observed effects be better accounted for by the processes proposed in CLT or an attentional focus explanation? In order to examine these questions, we assessed problem solving performance on transfer problems that were structurally different than training problems, and used a measure of schematic knowledge that is independent of problem solving performance.

Method

Participants

Fourteen undergraduate students enrolled in an Introductory Psychology course at the University of New Mexico participated in this study for partial course credit. None of them had previously completed a college-level statistics course. Half of the participants were randomly assigned to receive training with standard goal specificity problems (SGS), while the other half received training with reduced goal specificity problems (RGS).

Problem Solving Domain & Materials

The problem solving domain used in the present study was one-way analysis of variance (ANOVA). All problems used were relatively simple word problems that could be solved with the following three equations: $df_B = a - 1$, $MS_B = SS_B / df_B$, and $F = MS_B / MS_W$, where a = number of groups, df_B = between groups degrees of freedom, MS_B = between groups

mean square, SS_B = between groups sum of squares, F = F -ratio, and MS_W = within groups mean square.

All training problems gave values for a , MS_W , and F . Those used in the SGS condition asked to solve for SS_B , while those used in the RGS condition asked to solve for as many unknown values as possible. Notice that in both conditions successful solutions required participants to first solve for df_B and MS_B (in either order), and then solve for SS_B .

Structurally identical transfer problems for both conditions were identical in structure to the training problems received in the SGS condition during training in that they gave values for a , MS_W , and F , and asked to solve for SS_B . Structurally different transfer problems were different in structure from the training problems in that they gave values for different variables, and asked to solve for a different variable. Thus, structurally different transfer problems still required use of the same three equations to solve, but they required that the equations be used in a different order and that the equations be manipulated in a different way than was done during training.

A relatedness rating task was also used in which participants were asked to rate the relatedness of all pairwise combinations of the six statistics terms contained in the equations listed above on a 5-point scale (1="Not at all related", 5="Very related").

Procedure

All participants were tested individually in the presence of an experimenter. Participants were first asked to solve three training problems. During this training period, they were given a Rolodex containing separate note cards containing each of the three equations necessary for solution of the problems, as well as a calculator to perform computations. Participants were allowed five minutes to solve each problem. Within this time, the experimenter would immediately notify the participant if they made a mistake, but would not tell them the nature of the mistake. If the problem was not solved within five minutes, the experimenter would guide them to the solution. After solving a problem, participants went on to the next problem and could not refer back to previous problems.

Upon completion of the third training problem, participants were asked to complete the relatedness rating task, which took approximately five minutes. The equations were not made available to participants during completion of this task.

Next, participants were asked to solve four transfer problems (2 structurally identical, 2 structurally different). Approximately half of the participants in each condition were given the two structurally identical transfer problems first, while the other half were given the two structurally different transfer problems first. Participants were again given the necessary equations, and problem solving proceeded as during training.

Results

Separate one-way ANOVAs were used to compare the SGS and RGS conditions on time to solve each of the training problems, and on time to solve structurally identical and structurally different transfer problems. Additionally, separate one-way ANOVAs were used to compare the number of various kinds of links found in the structural knowledge representations of participants in the SGS and RGS conditions. A .05 significance level was used for all tests.

Training

Participants in the RGS condition solved the first two training problems significantly faster than those in the SGS condition, $F(1,12)=5.03$, $p=.045$ and $F(1,12)=6.89$, $p=.022$, respectively for the first and second training problem. This is consistent with the idea that SGS problems require greater cognitive load, and should therefore require more time to solve. There was no significant difference between the SGS and RGS conditions on time to solve the final training problem, $F(1,12)=1.52$, $p>.10$, suggesting that participants in both conditions had acquired similarly efficient solution procedures by the end of training (see Table 1).

Table 1: Time (in seconds) to solve training, structurally identical transfer (S-I), and structurally different transfer (S-D) problems as a function of training condition.

Problem	SGS	RGS
	Mean (SD)	Mean (SD)
First training	300.00 (0.00)	238.14* (72.94)
Second training	219.00 (58.25)	145.00* (46.59)
Third training	139.00 (50.39)	106.29 (48.85)
S-I transfer	108.29 (31.30)	99.64 (55.44)
S-D transfer	254.93 (45.27)	164.93 (78.52)*

* $p<.05$

Structurally Identical Transfer

There was no difference between the SGS and RGS conditions on average time to solve structurally identical transfer problems, $F<1$ (see Table 1). Apparently, both conditions learned to solve problems of the structure that they were trained on equally well. Although CLT (both the limited schema and general schema views) had predicted better performance from the RGS condition, it is possible that the task was too easy to disrupt learning in the SGS condition. If so, then we would expect no difference on the structurally different transfer problems.

Structurally Different Transfer

Participants in the RGS condition solved the structurally different transfer problems significantly faster than those in the SGS condition, $F(1,12)=6.90$, $p=.022$ (see Table 1). This suggests that although both conditions learned to solve problems structured like the training problems equally well, those in the RGS condition gained qualitatively different

knowledge that allowed superior transfer to structurally different problems. This is in contrast to both the limited schema and exemplar views. Schemas comprised of knowledge of problem states encountered during training and associated operators would not apply to the structurally different transfer problems, since these problems involved different problem states. Neither would exemplar solutions acquired during training apply, since the structurally different transfer problems required different solutions. Based on these results, it appears that the schematic knowledge acquired during RGS training is more general than previously thought.

Structural Knowledge

Participant's relatedness ratings were submitted to the Pathfinder scaling algorithm to generate a knowledge network for each (for a review of Pathfinder, see Schvaneveldt, 1990). These networks were then analyzed for the number of: (1) critical links with the training goal, (2) irrelevant links with the training goal, and (3) critical links with non-goal concepts (see Table 2).

There are two critical links with the training goal (SS_B) found in the expert network, one with each of the subgoals, (df_B and MS_B). There was no difference in the mean number of these links possessed by participants in the SGS and RGS conditions, $F<1$, as predicted by an attentional focus explanation.

Four other irrelevant links (i.e., those not found in the expert network) with the training goal are possible. As predicted by the attentional focus explanation, participants in the SGS condition possessed significantly more of these irrelevant links than participants in the RGS condition, $F(1,12)=7.59$, $p=.017$.

Four other critical links, not involving the training goal, are present in the expert network. Of these links, participants in the SGS condition possessed significantly fewer than participants in the RGS condition, $F(1,12)=7.36$, $p=.019$, again consistent with predictions made by the attentional focus explanation.

Taken together, these structural knowledge results are consistent with an attentional focus explanation. Under SGS training, attention is focused on the goal, resulting in both relevant and irrelevant associations being made with the goal, at the expense of other critical schematic associations. RGS training, on the other hand, focuses attention precisely where it is needed for schema acquisition, on the local relations described by the equations.

Table 2: Number of links as a function of training condition.

Link type	SGS	RGS
	Mean (SD)	Mean (SD)
Critical, with goal	1.14 (.69)	1.43 (.53)
Irrelevant, with goal	1.57 (.98)	.29 (.98)*
Critical, with non-goals	1.71 (.76)	3.00 (1.00)*

* $p<.05$

Discussion

The results of the current study support and extend previous studies of the goal specificity effect. Reducing the specificity of training goals led to problem solving advantages. However, the advantage was found on transfer problems that were structurally different than training problems. Thus, it is argued that the schematic knowledge that is more readily acquired under RGS than SGS training is more general than previously considered.

These results are consistent with Owen and Sweller's (1985) contention that schema acquisition involves learning abstract principles. It appears that these principles are not tied to problems of a specific form. With respect to the structural knowledge measure employed in the current study, results suggest that the acquired relational information is not unidirectional. Such findings are important for theories of expertise, since we expect expert-like schemas to be applicable to a wide range of novel problems, not just those encountered in the past. If schemas were limited, then experts would gain no advantage at solving novel problems. The very basis for schema theory is that experts possess not only more knowledge through experience, but also better structured knowledge.

The finding that RGS training leads to the acquisition of general knowledge that can be transferred to structurally different problems than encountered during training is pedagogically important as well. Despite being one of the foremost goals of educators, the difficulty in obtaining transfer to non-isomorphic problems has been well documented (e.g., Gick, & Holyoak, 1983).

The structural knowledge results obtained in the current study are consistent with an attentional focus explanation for the goal specificity effect. It should be pointed out that although the attentional processes invoked by this explanation are described in CLT, they are not dependent upon greater cognitive load being present in the SGS condition. Instead, the present results can be explained by SGS training focusing attention on pedagogically irrelevant relations, and RGS focusing attention towards pedagogically relevant ones. This explanation is similar to one advanced by Miller, et al. (1999). They had participants learn about electrical fields by interacting with a microworld called Electronic Field Hockey (EFH). Participants who practiced moving a puck around the EFH workspace in a no-goal condition performed better on a subsequent test of declarative and procedural knowledge of electrical fields than those who practiced by directing the puck around obstacles and into a specific goal. However, participants who practiced by trying to make the puck follow a well-specified path denoted by a line leading around obstacles and into a goal, performed almost as well as those in the no-goal condition. Miller, et al. (1999) posit that eliminating the goal worked by requiring interaction with the pedagogically relevant aspects of EFH, just like the specific-path condition. In other words, the specific-path condition directs attention away from the ultimate goal toward a series of more immediate subgoals. By directing attention from

more distant goals, it can be focused on local relations involved in solving current subgoals. Similarly, eliminating distant goals altogether allows attention to be focused on immediate local relations, which turn out to be the pedagogically relevant ones.

The results of Miller, et al. (1999) may also be explained by a cognitive load interpretation. If following a specific path shifts attention completely away from the ultimate goal, then the task becomes one of meeting a continuous series of smaller goals. If attention is directed at solving each of the immediate goals (i.e., staying on the path), and if each of these small goals can be solved without use of a means-ends strategy, then the specific-path condition would require no more cognitive resources than the no-goal condition. It may be argued that problem solvers solving no-goal problems do adopt a strategy of setting a series of small goals for themselves that can be solved in a forward-chained manner.

Thus, although neither the present results nor the results of Miller, et al. (1999) require an explanation based on cognitive load, they do not rule it out as a possibility. One way to resolve the issue concerning whether RGS training works due to reduced cognitive load or to a pedagogically relevant focus of attention would be through a dual task paradigm. Problem solvers could be asked to solve RGS problems either while concurrently performing another resource demanding task or not. If the concurrent task interferes with learning in a manner consistent with SGS training, then the cognitive load explanation would be justified.

Overall, this study indicates that eliminating specific goals during training can benefit schema acquisition, and that this advantage is more general than previously considered. Training on problems with non-specific goals allowed better transfer to structurally different problems. It is concluded that non-specific goals allow learning pedagogically relevant, local relations, as opposed to standard problems which interfere with such learning. It is suggested that problems with non-specific goals provide this advantage by focusing attention on relations necessary for schema acquisition.

Abstract

In 1856, Faraday conducted a long series of experiments on the color of gold. We report replications of some of his experiments, permitting an understanding of his response to an important anomaly and the resulting conceptual reorganization of his ideas.

Introduction

In 1856, Michael Faraday (1791-1867) carried out nearly a year's worth of research on the optical properties of thin gold films (Faraday, 1857). In the course of this work, he discovered colloidal gold (the first metallic colloid) and what is now known as the "Faraday-Tyndall Effect," the fact that colloids scatter light. Colloids were an unexpected consequence of his attempts to understand the unusual color properties of thin films of gold. These, in turn, were an important extension of his earlier attempts to understand the interaction of light and matter, and his speculations about the force-centered character of matter (James, 1985; Tweney, 2002).

The present project was initiated by the discovery of over 600 surviving microscope slides and other specimens made by Faraday as part of his research, and now held at the Royal Institution in London (Tweney, 2002). The slides are numbered and indexed in Faraday's Diary and represent nearly the complete set of metallic film specimens used by Faraday in 1856. However, only a few of his colloidal specimens (and none of his precipitates) survived; thus, one goal of the present effort is to restore lost specimens for analysis. Replication is also important even for specimens that still survive – Faraday often subjected the specimens to destructive and/or damaging manipulations, and these manipulations also need replication. Four general procedures used by Faraday are currently being replicated by our group: (1) Precipitation of gold from solution, (2) "Deflagration" of gold wire, that is, exploding gold wire using sudden surges of current, (3) Producing colloids using reduction by phosphorous,

and (4) Producing thin metallic films of gold using reduction by phosphorous.

Here we present our replications of Faraday's precipitates. Besides restoring for analysis certain lost specimens, these allow insight into the "tacit knowledge" implicated in their preparation. More importantly, preparation of our own precipitates allowed analysis of aspects of Faraday's research previously hidden from view, helping to account for an important conceptual change.

In earlier accounts of Faraday's research, our group examined the way in which Faraday experimentally traversed a problem space of hypothesized and real results during his discovery of electromagnetic induction in 1831 (Tweney & Hoffner, 1987). Our analysis suggested that Faraday used a relatively narrow search strategy in the 1831 experiments, one in which potentially disconfirming evidence was initially ignored and only evidence which supported expectations was pursued. In later stages of the research, he made explicit attempts to disconfirm. This "confirm early-disconfirm late" strategy resembled heuristics observed by Klahr in the "Big Trak" studies (Klahr, 2000) and by Dunbar (1995) in an "in vivo" study of laboratory molecular biologists.

Not all aspects of scientific thinking can be characterized as search through multiple problem spaces (Kurz & Tweney, 1998), and this is especially true of Faraday's work. For example, Gooding (1990) replicated Faraday's 1821 discovery of electromagnetic rotations and argued that identification of circular rotatory motions could only have come about by means of an "eye-hand-brain" interaction of a very dynamic character. Rather than "testing hypotheses," Faraday instead had to make the meaning of the otherwise chaotic appearances presented by the experimental apparatus. Similarly, Cavicchi (1997), partly by conducting replications, showed that Faraday's experimentation during his 1845 discovery of diamagnetism proceeded "not by progressively refining

explanations, but by exposing previously unnoticed ambiguities in the phenomena, and uncertainties in interpretation. This exposing deepens the space of [his] confusions" (1997, p. 876). For Cavicchi, such "confusions" (perhaps in response to a surprising result) are a crucial aspect of the pattern-finding involved in discovery. She was further able to show that Faraday's "confusions" resembled those of a student exploring the relationships between bar magnets and iron needles.

Our earlier examination of two of Faraday's papers, one on acoustic vibrations and one on optical illusions of motion, suggested that Faraday's constructive perceptual processes imply a continuum of developing representative explicitness. This continuum began with the perceptual rehearsal of remembered events, proceeded through the construction of "inceptual" representations (that is, representations that abstract away potentially irrelevant features, with an effort to "see" what the results would look like), and finally resulted in a mental model that even included non-perceivable features of phenomena (Tweney, 1992; Ippolito & Tweney, 1995). Again, Faraday appeared to be using an "eye-hand-mind" dynamic in constructing new spaces. Similarly, Nersessian (1999) argued that Faraday and Maxwell used analogies and imagery in a process of generic abstraction, itself important in conceptual generation and change.

Andersen (2002) argued that conceptual reorganization in science often requires a semantic shift, in which exemplars change category. She showed that such change was an important part of the resolution of anomalies in particle physics in the 1930s. The present paper extends the scope of Andersen's argument, by showing that Faraday's work on precipitates was an active source of a crucial conceptual change near the beginning of his 1856 research on gold, perhaps dependent upon the "confusions" engendered by some of the appearances of gold (described below). The dynamics of the reorganization depended upon "epistemic artifacts" constructed by Faraday to serve as active agents in exploration of a new domain.¹

A distinguishing feature of all of Faraday's research was his determination to produce phenomena of such clarity that his explanations of the phenomena would be transparent to his audiences. "Seeing was believing" in a deep sense for him (see, e.g., Fisher, 2001; Gooding, 1990), and his attention to anomalies in the present case is especially important in explaining the cognitive dynamics of the research. Thus, our replications can potentially contribute to the understanding of the cognitive dynamics of visual representation in scientific

research generally (see, e.g., Kulkarni & Simon, 1988; Trickett, et al., 2000).

Why Gold?

Gold films interested Faraday because thin transparent gold films manifest a different color by transmitted light than by reflected light; green, blue, and purple are the most frequent transmitted colors for gold leaf. Faraday thought that gold was therefore a good place to look for insight into the interactions of matter and light. For him, the profoundly interesting question concerned the manner in which such very thin (and apparently continuous) films could so alter light. Although he failed to achieve a definitive answer to this question, he successfully showed that many of the optical properties of metals in general could be produced by the interaction of discrete particles with light. His discovery of gold colloids was an integral part of this argument.

A colloid is a suspension of finely divided particles of a substance held in suspension in a fluid. Colloids differ from solutions in that solutions represent ionized particles of atomic size, carrying an electrical charge. Ions, the particles that form a solution, are much smaller than colloidal particles and affect light in different ways. Faraday's discovery that metals could form colloids was a breakthrough, especially since he also showed that the particles were pure gold, chemically identical to the metal films. Note also that colloids differ from precipitates, which are formed of even larger particles than colloids. If a reducing agent is added to a solution of a gold salt, then metallic gold (Au) is precipitated as a solid. In modern notation;

Because the particles in a precipitate are far larger than those in a colloid (sometimes being visible to the unaided eye), they settle quite quickly. Colloidal particles (which are far too small to be visible) do not settle because, as Faraday speculated, they are lightly bonded to a "cloud" of ionized particles that repel the surrounding fluid media.

The chemistry of precipitates is more complex than the formula given above suggests, since gold chlorides exist in solution as $[\text{AuCl}_4]^-$ ions and various hydrolyzed ions as well.² These more complex species and reactions were not known to Faraday. As we discovered, however, the complexity of the reactions is reflected in a very complex phenomenology when gold salts are actually used. We had expected precipitating a gold salt to be a simple and straightforward process -- a "warm-up" exercise for us (as we thought it may have been for Faraday). In reality, our replications opened a new aspect of Faraday's work on gold, one not visible in the text of the diary itself. In the present paper, we describe our replications of Faraday's precipitates and compare them to colloids and solutions.

¹ The term "epistemic artifact" was used by Tweney (2002) to suggest a blending of the term "cognitive artifact" used by Zhang & Norman (1994) and "epistemic thing" used by Rheinberger (1997).

² See Puddephatt, 1978, for this and other details of the reactions of gold.

Faraday's Diary

Faraday's diary is well known because of its relative completeness, an aspect which permits reconstruction of his research practices (e.g., Steinle, 1996). In some cases, however, as in the case of his research on gold, much of the diary is hard to interpret by itself, since the visual context of Faraday's work is absent. As we show, even with that visual context present (in the form of the surviving specimens), there is more to be learned from the "manual" aspect.

Faraday wrote 1160 numbered entries on his gold research, roughly 300 manuscript pages dated from the 2nd of February, 1856 to the 20th of December (Martin, 1936). The distribution of entries (Figure 1) is roughly bimodal, the greatest density of entries occurring at the beginning of the series and toward the end. The first 47 entries (in the first peak of the distribution) are summaries of previous notes. They also include several dozen entries in which Faraday speculates on possible experiments, much as he had earlier kept an "idea book" to record possible studies (Tweney & Gooding, 1991). Faraday's (1857) published paper on the topic was submitted on November 15, 1856 and read before the Royal Society on February 15, 1857. Indeed, the character of the entries in the second peak suggests that he was "mopping up" prior to ending the research – conducting some necessary control experiments, trying again to resolve some inconsistencies, replicating key preparations, and so on. His work with precipitates occurs near the beginning of the series, on February 5, and appears to record the first laboratory work on gold conducted in his own laboratory (earlier entries describe gold film preparations made at the home of a friend, Warren De La Rue; see Tweney, 2002). Thus, one question is why precipitates constituted the first task undertaken by Faraday.

It has been suggested (e.g., Williams, 1965) that Faraday's work on gold in 1856 manifests his "declining powers" (whether due to aging alone or to the effects of the many toxic exposures he was subjected to over the years). This judgement may stem,

in part, from the seeming aimlessness of the precipitation experiments, especially since these occur at the beginning of the first burst of activity. Since the precipitation reaction of gold was long-familiar by 1856, Faraday could learn nothing new here and the text of the Diary alone does not indicate why he initiated his gold research with what seems like a rather prosaic procedure. As we show, however, the experiments with precipitates were far from trivial – by conducting the replications, we were able to detect a "confusion" that served a heuristic role in the important step of arguing that the colors of gold are due to particles interacting with light.

Method

Faraday is vague about exactly how he prepared the precipitates used in his research. In the Diary he indicated only that he "Prepared a standard weak solution of Gold" and a "standard solution of proto sulphate of Iron ... consist[ing] of 1 vol. saturated solution at 54° F. plus 2 vols. Water, and a little sulphuric acid to keep all in solution during the changes" (Entry #s 14291 & 14292, 5 Feby. 1856). "Proto sulphate of iron" is "Ferrous Sulfate" in modern terms, and the fact that it was saturated allowed reproduction of the exact substance used by Faraday. But no clue is offered about the "standard weak solution of Gold." Thus, its concentration is unknown and, more importantly, because of the complex chemistry of gold salts and the solution processes by which they dissolve, several possibilities had to be explored for how to prepare the precipitates.

Today, "Gold Chloride" is typically sold in one of two forms; as "Gold (III)," that is, as gold in the valence state +3, in the form of "Tetrachloroauric Acid" (HAuCl_4), a yellow crystalline substance, or as "Gold (I) Chloride" (AuCl ; valence state +1), in the form of yellowish-white crystals. Each was tried in turn as the basis for gold ion in solution, but neither proved satisfactory, in part because each is unstable. Further,

Faraday's Diary Entries: 5 Feb 1856 - 20 Dec 1856

Figure 1

dissolving each in water is problematic; each leaves a precipitated deposit. In the case of tetrachloroauric acid, this is probably pure gold, an expected product when the substance hydrolyzes, but (barring extensive analytic procedures) we were unable to determine if the deposit was the expected gold or simply an undissolved portion of the original crystals. As a result, we could not be sure of the strength of the solutions we were preparing. "Gold (I) Chloride" (AuCl), in the presence of water, oxidizes to the III valence state. This substance seemed to dissolve readily, but again with traces of a deposit. Here again, knowing the strength of the resultant solutions was difficult. Accordingly, we decided to begin with pure gold, dissolving it in such a way that we could be sure of at least the quantity of gold in the solution.

Pure gold wire (0.025" diameter, 99.99%) was obtained from a vacuum technology supply house.³ Aqua Regia, a 3:1 combination of hydrochloric acid and nitric acid, was used to dissolve a 3.5 cm length of the wire, weighing 217 mg, to create gold chloride solution.⁴ Fifteen minutes after addition, the gold wire completely dissolved in the acid. The solution was then boiled in order to remove the hydrochloric and nitric acid. Water was added as needed to keep a constant volume of about 10 cc. The solution was boiled until the odor of the acids and the nitric oxide byproduct (all of which are pungent in even slight quantities) was no longer present.

To produce a gold colloid we used a modern method, the reduction of gold chloride solution by citrate ion (producing such colloids using Faraday's methods is part of an ongoing study and will be reported later). Gold (III) chloride (i.e., tetrachloroauric acid) (3 mg) combined with 10 ml of water produced the gold chloride solution. Gold and excess gold chloride remained at the bottom of the container. Ten mg of sodium citrate, a source of citrate ion, was dissolved in 10 ml of water. The gold chloride solution was agitated with a magnetic stirrer and heated to boiling temperature. Citrate solution (0.015 ml) was slowly added to the gold chloride and reacted immediately, producing a very pale slate-blue solution. Over the course of forty seconds the color of the solution evolved from slate-blue to amethyst to ruby red. When cooled, the product proved stable over many months. Although we cannot be sure of the quantities of gold that are actually in colloidal form, the properties of our colloid were exactly as described by Faraday.

³ Gold wire, because of its malleability and lack of reactivity, is used as a component in high-vacuum O-ring seals. Jewelry gold, unfortunately, is always alloyed with other metals.

⁴ Unlike other metals, gold will not dissolve in hydrochloric acid (HCl) alone because it requires both an oxidant and a ligand donor (Cl^- , in this case). When Aqua Regia is used, the result is AuCl_4^- in solution and gaseous nitric oxide (NO).

The reduction of gold chloride solution by ferrous sulfate solution was used to form gold precipitates. A saturated solution was prepared by dissolving crystalline ferrous sulfate (FeSO_4) in heated water. When cooled, three drops of ferrous sulfate solution were added to 5 ml of gold chloride solution. No immediate reaction was apparent, but on the following day a yellow-orange residue of metallic gold had settled at the bottom of the experiment tube and could be re-dispersed by shaking.

Results

The three preparations showed the expected appearance in ambient (room) light; the solution was a clear, deep yellow fluid, the colloid was a clear ruby-red fluid, and the precipitate, when shaken, was a cloudy yellow-gold suspension in which individual particles could be seen in motion, and in which occasional glints of bright metallic gold could be seen. Except for the overall color, the solution and the colloid appeared to be very similar, while the shaken precipitate had a very different appearance.

The relative similarity of the three changed, however, when directional lighting was passed through the fluids. The principal results are summarized in Figure 2, which shows the effect of a parallel beam of light produced by a fiber-optic illuminator (entering from the left) on our prepared gold colloid, a solution of gold chloride, and the precipitated gold preparation, respectively. The overall colors of the preparations are not shown here, but can be viewed at <http://personal.bgsu.edu/~tweney>. The precipitate was shaken just before the photograph was taken. Note that the colloid shows a bright "Faraday-Tyndall Effect," that is, light is scattered to the side, illuminating the path of the beam through the colloid.

Figure 2. Colloid, Solution and Precipitate

The colloid (a ruby-red transparent fluid) tinges the scattered light a faint pink. The solution scatters no light, only some small reflections from the sides of the glass test tube being visible in the photograph. The precipitate scatters light rather more broadly than the colloid, although some of that is an incidental result of the widening of the initially parallel beam of light into a cone, as a result of its passage through the two prior

preparations. The overall color of the scattered light from the precipitate is a yellowish-gold, and individual particles are easily visible. Obviously the colloid and the precipitate resemble each other most closely under these optical conditions, in contrast to the appearances in ambient light. Although there is no record in the diary of Faraday placing these three in one context (as we have done in Figure 2), it is clear that he was attending these differences very carefully – they constituted part of the basis for his conclusion that the colloids were in fact metallic particles of gold.

Conclusions

The change in apparent similarity of the three kinds of preparations when transmitted light is compared to ambient light (Figure 3) suggests a possible “confusion” (Cavicchi, 1997), and the need for a reorganization of the phenomenological domain of “divisible gold” (as Faraday referred to it in the 1857 paper). This confusion suggests an explanation for why Faraday began with precipitates on February 5, an explanation that corresponds with what Faraday does say in the Diary.

Figure 3. Taxonomy of Similarities

From the Diary, we learn that Faraday had visited De la Rue the week prior to February 5th, and the two had examined some gold leaf through the microscope; Faraday recorded this visit in his first diary entry on gold (#14243, 2 February 1856). On the 2^d, Faraday received some thin gold films prepared by De la Rue, who had used phosphorous to reduce the gold. On the 6th (one day after preparing his precipitates), Faraday established a careful optical method for the examination of precipitates, and recorded that, in the evening, he went to De la Rue's again, and observed how the thin gold films were made. At this point, Faraday noticed something odd; “A very fine red fluid is obtained [from] the mere washing” (Diary, #14321). This, of course, was a colloid, and Faraday saved the fluid,

returning to it two weeks later on the 18th (#14437), after his experiments with precipitates and his first examinations of thin films. At that point, he was able to ask; “... the question is, is it [i.e., the gold] in the same state as whilst apparently dissolved in the fluid” (#14437, emphasis in original). It is interesting to note that during this 16 day period he referred to the red fluid using two terms interchangeably, “fluid” and “solution”. Only later could he be sure that the red fluid was not a solution, although he must have had the idea very early.

The sequence of his ideas then must be something like the following. He first compares thin films (which he suspects are gold in a continuous state) to the precipitates, which he knows to be discrete particles. Since gold in a continuous state changes appearance in transmitted light and reflected light, he develops an “optical method” for examining precipitates under the same two conditions. Note that, to prepare the precipitates, he must have had before him the clear solution of gold chloride. Then, at De la Rue's, he explicitly notices the clear red solution and this must have suggested a comparison. He knew that the substances used to produce the clear red solution (phosphorous, carbon disulfide, and a gold chloride solution) produced metallic gold. But why then did it look like a solution? Resolving this “confusion” led him to examine the red fluids more closely – and it would be a natural extension to use both transmitted and ambient light, just as he had done with the precipitates. And the transmitted light (as our Figure 2 shows) would make the red fluid look very different from the clear solution. A real anomaly had been found, and a reorganization became necessary; the “red fluid” must be gold in a “divisible state,” like the precipitates.

There was, of course, still much to do. More work was needed to explore the new optical effects, to examine other kinds of divisible gold (e.g., that produced by exploding gold wires), to examine other substances, and, most importantly, to explain the differences in the color of light produced by gold in different states (a goal only partially realized). Yet the anomalous appearance of the red fluids at the beginning of the series of experiments provided Faraday with a first important clue to the kind of inquiry he would need to make. Far from constituting a record of “declining powers,” the replications allow us to see that Faraday's ability to notice and exploit an anomaly was undiminished in 1856.

Further, our replications revealed that the precipitation experiments are more important than can be discovered by examining the diary records alone, because their role in recognizing the divisible state of colloidal preparations is not evident otherwise. The text of the diary alone does not reveal what was obvious, visually, to Faraday – and was obvious to us only when

present as the result of our own "makings." Only in this fashion could we have noted a conceptual change reminiscent of that seen by Andersen (2002) in her analysis of 20th century particle physicists.

Faraday's gold research in 1856 provided Faraday with mental models based upon new conceptions about the interaction between thin gold films and light. And the differing visual properties of colloids, solutions, and precipitates were a crucial first step, because they showed that the particles of gold had specific optical properties. These in turn led Faraday to reevaluate his previous views of the distinction between continuous and "divisible" matter. Thus, there are similarities between the conceptual reorganizations we observed by replicating Faraday's precipitation experiments, and the larger reorganizations that constituted the outcome of the entire 1856 series of studies. Further replications and text analysis are in progress to extend the reach of this conclusion.

Abstract

To see is to believe. A picture is often worth a thousand words in everyday communication settings. A graphical representation actually “talks” in such communication, integrated with some other representation systems like spoken language. Because of its power, however, a graphical representation can affect the way people grasp a target situation it describes. This paper presents an empirical investigation of language usage in graphical communication. Drawing on actual dialogue data, we show that the configuration of graphics affects linguistic expressions of motion when people collaboratively work on a task. This effect of graphics on language usage demonstrates that the configuration of graphics has an influence on perspectives in event conceptualizations.

Introduction

Daily communication is by nature multi-modal, and graphics often serve as strong visual aids for information exchange. People communicate with each other effectively by integrating information from linguistic and graphical sources (Neilson and Lee (1994); Umata, Shimojima, and Katagiri (2000)). People grasp described situations via graphics, taking advantage of their “handiness.” Because of this role they play, however, the way people grasp target situations can be affected by graphics.

Recent investigations have demonstrated that the perspectives of spatial descriptions and linguistic expressions show some correspondence. Levinson (1996) observed that some languages make almost exclusive use of absolute coordinates while European languages tend to use egocentric or relative coordinates, reflecting people’s strategies for spatial memory and inference. Taylor and Tversky showed that there are three perspectives of spatial descriptions (i.e. *a gaze tour/a route/a survey*) that roughly correspond to the frames of reference distinguished by Levinson in a linguistic method.

It has also been observed that the existence of graphics provides two graphics-based perspectives in addition to those used in only describing a world, and that there is a trade-off between cognitive costs and alignment-failure-robustness (Umata, Katagiri, and Shimojima (2002)). One of those perspectives is called the Observer-to-Graphics Perspective, in which people conceptualize the

target events from the viewpoint of the observer relative to the graphics. Suppose one says: “From Baker Street, we’ll travel on the Bakerloo Line and then go right at Oxford Circus to Holborn” while holding the map of the London Underground shown in Figure 1. The movement is described from the viewpoint of the observer relative to the map. On the other hand, if one says: “From Baker Street, we’ll travel on the Bakerloo Line and then go left at Oxford Circus to Holborn,” the speaker “goes into” the map world as an imaginary agent, taking the other perspective called the Protagonist Perspective.

When people see and talk about world situations through graphics, it is quite likely that the features of the graphics affect the way people conceptualize the target situations. In this research, we studied how the availability and configuration of graphics affect language usage in communication and problem-solving. We focused on the influence of graphical representations on the conceptualization of motion events.

Suppose that John and Mary are at the Goodge Street tube station, discussing where to have dinner together. Mary might suggest a place by saying (1) below, but she would not do it by saying (2):

- (1) Let’s go down to Waterloo Station on the Northern Line and eat at Livebait.
- (2) Let’s come down to Waterloo Station on the Northern Line and eat at Livebait.

The current position where the two people are located becomes the reference point of the movement in this case, and the movement can only be conceptualized as a movement away from the reference point, and hence the use of “go.” Suppose, on the other hand, that John and Mary are discussing their evening plans over the map of the London Underground shown in Figure 1. Mary could use, in this case, either (1) or (2). The availability of the map and the configuration of icons on the map affect the conceptualization of the movement here: the nearness of the Waterloo Station icon from them makes it possible for her to conceptualize the movement, in addition to the previous distal movement conceptualization, as a movement *in the map-world* toward the reference point, their current position. Graphical representation can have an influence on language usage.

The use of “come” in (2) is possible because the map and the graphical objects contained in it are readily avail-

¹This research was supported in part by the Telecommunications Advancement Organization of Japan.

Figure 1: Route Map of London's Underground System

able to the speaker as a resource to formulate messages to be communicated and problems to be reasoned about. The locations and arrangements of objects can be expressed in terms of the relationships between graphical objects and the speaker, as well as those between objects themselves and the speaker. This availability, or the ease of accessibility, of graphical representations should work to amplify our communicative and reasoning capabilities by providing us with a novel set of possibilities for constructing perspectival event conceptualizations.

We investigated the effect of graphical representations on perspectival event conceptualizations through an empirical analysis of the use of motion verbs in actual two-party task-oriented dialogues that make use of diagrams. We first outline, in the next section, the classification of the types of perspectival conceptualizations available in communications that involve graphical representations. We then examine, in the following section, the Japanese dialogue data from our corpus involving a "Missionaries and Cannibals" type puzzle. We found that the configuration of graphics affects the way people grasp the target situations and that the perspectival conceptualizations of the graphical objects are more prominent than those of the real-world objects they represent.

Perspectives in Graphical Communication

In graphical communication, graphical representations work as "windows" through which we can see the target situations the graphics describe. However, they also serve as information processing "sites" because we can take advantage of their handiness. Graphical representations are so deeply ingrained in how we grasp and describe target situations that their existence raises the possibility of setting novel perspectives in conceptualizing events. Two such perspectives were observed in Umata, Katagiri and Shimojima (2002), in addition to two perspectives concerned solely with the target world. There

are four possible categories of perspectives on motion events in graphical communication.

(a) Observer-to-World Perspective

A movement is taken as a movement in the real world and conceptualized from the viewpoint of the observer within the real world. This perspective is concerned solely with the real world.

(b) Agent Perspective

A movement is taken as a movement in the real world and conceptualized from the viewpoint of the agent of motion. This perspective is concerned solely with the real world.

(c) Observer-to-Graphic Perspective

A movement is taken as a movement in the map space and conceptualized from the viewpoint of the observer relative to the map. This perspective concerns both the real world and the graphic space and creates a bridge between the two.

(d) Protagonist Perspective

A movement is conceptualized from the viewpoint of an imaginary agent in a narrative world. In graphical communication situations, a graphic provides the narrative domain for this perspective. The agent can be identified with either the speaker or the listener. This perspective belongs solely to the narrative world.

The first two categories are perspectives concerned solely with the target world, which can also be observed in communication without the use of graphics. When you say "John is coming to my place from Goodge Street" without a map, you are taking the Observer-to-World Perspective. If you are actually driving to somebody's place, you might say "I'm now going to the right-hand side of Piccadilly Circus," taking the Agent Perspective. If you are explaining the way to somebody via a cellular phone, you might say, "Go south and turn left at Leicester Square," taking the Agent Perspective of the person to whom you are talking.

In graphical communication, the latter two perspectives are available in addition to (a) and (b). Examples from the HCRC Map Task Corpus analyzed in Umata, Katagiri and Shimojima (2002) are shown below.

HCRC Map Task Corpus

The examples shown in the following sections are from the HCRC Map Task Corpus. This map task is a cooperative one involving two participants. The two speakers sit opposite one another, and one speaker gives instructions for a route to the other. Each has a map that the other cannot see, and a route is marked on the Instruction Giver's map while no route is marked on that of the Instruction Follower. The speakers are told that their goal is to reproduce the Giver's route on the Follower's map. Their maps are not exactly identical and the speakers are

Figure 2: Movement described in (3)

told this explicitly at the beginning of their first session. It is, however, up to them to discover how the two maps differ. The maps describe fictitious areas.

Observer-to-Graphic Perspective

First, consider the following utterances:

- (3) (The Giver is showing the Follower the movement shown in Figure 2.)

Giver: Okay? Now you need to drop straight down towards the gazelles.
 Follower: Right, coming in at the top of them.
 Giver: That's right, and then go round the bottom of the gazelles.
 Follower: On the left-hand side?
 Giver: And head off to the right-hand side ... So you go under the gazelles

The expression "drop straight down to" would not have been suitable without a map. It describes the motion from the Observer-to-Graphic perspective, making use of the spatial relation on the map. Other spatial expressions ("at the top of," "bottom of," "right-hand side," and "under") also describe the spatial relation of the target situation via the graphical relations. For example, "go round the bottom of the gazelles" does not mean actually going under the gazelles in the target situation. Also, notice that the deictic spatial expression "to the right of" is based on the Observer-to-Graphic Perspective. It would have been "to the left-hand side" if the giver was taking the Protagonist Perspective.

Protagonist Perspective

Now we will examine the examples of the Protagonist Perspective shown in (4):

- (4) (The Giver is showing the Follower the movement shown in Figure 3.)

Giver: Then down.
 Follower: What do you mean down? Towards the bottom of the paper?
 Giver: Uh-huh
 Follower: Uh-huh. Do I ... do I go by the collapsed shelter?
 Giver: Uh-huh
 Follower: Uh-huh
 Giver: And then ... so that ... until you've got ...
 Follower: The collapsed shelter's on my right?
 Giver: Uh-huh

Figure 3: Movement described in (4)

Follower: Right

Giver: And then go round to your left

Follower: My left?

Giver: As you're the wee guy

The spatial expressions "on my right," "to your left" and "my left" are clearly based on the Protagonist Perspective. If the speakers were talking based on the Observer-to-Graphic Perspective, they would have said "on my left," "to your right" and "my right," respectively. The giver confirmed it with the utterance "as you're the wee guy," introducing an imaginary agent explicitly. Thus, we can find many such expressions spoken from the two graphic-based perspectives in communications that make use of graphics.

Perspectives and Alignment of Coordinates

We have observed that the existence of graphics provides two novel perspectives, namely the Observer-to-Graphics Perspective and the Protagonist Perspective. The former requires less cognitive resources because one can grasp motion events as seen on graphics. This perspective works if the coordinates are firmly aligned between speakers. However, misalignment of coordinates leads to serious miscommunication. On the other hand, the Protagonist Perspective is robust against misalignment, because conversation participants "go into the graphics," and the spatial relations between the actual speakers and their graphics are not crucial in this perspective. Such a "trade-off" between description cost and misalignment robustness was actually observed in the HCRC Map Task Corpus (Umata, Katagiri and Shimajima (2002)).

Dialogues Involving a "Missionaries and Cannibals" Type Puzzle

We have observed that the availability of graphics provides a novel set of perspectives based on graphics. Because people "see" the target situations via graphics from those perspectives, it is quite likely that the features of the graphics affect the way people conceptualize the target situations.

The dialogue data analyzed in this section were taken from two collaborative problem solving experiments that involved back-and-forth movement. Another important feature of this task was that it involved two real-world places that subjects were familiar with. We also examined how much effect the Observer-to-World Perspective had on the usage of motion verbs.

Motion Verbs in Corpus

Verbs like *come* and *go* reflect a speaker's reference point, as shown in (1) and (2). *Go* indicates motion to a location that is distinct from the reference point. *Come* indicates motion toward the reference point².

The Japanese language also has a pair of motion verbs similar to English *come* and *go*: *kuru* and *iku*. *iku* (go) and *tsurete-iku* (take) indicate motion to a location that is distinct from the reference point. *kuru* (come) and *tsurete-kuru* (bring) indicate motion toward the reference point³. *Iku*-type verbs are used more widely than *kuru*-type verbs in the sense that the former expresses movements that are neutral with respect to the reference point locations. There are several verbs that can be classified into these two classes. We examined the usage of these two classes of verbs in the following two experiments.

Data

The data analyzed here was gathered from experiments involving problem solving. In this task, two subjects collaboratively worked on a "Missionaries and Cannibals" type puzzles using a diagram given to them. The structure of the puzzle was basically the same as the original one, except that it involved two actual places that the subjects were familiar with. The time limit was seven minutes.

The subjects recruited from local universities were seated in separate, soundproof rooms and worked together as a pair using a shared virtual whiteboard and a full duplex audio connection. The diagram was shown on their whiteboards, and the subjects could draw and erase freely except that they could not erase the original diagram. All inputs to the screen were by stylus, and any writing or erasing by one participant would appear simultaneously on the partner's screen. A pointing action with the stylus was shown by a cursor on the screen, and the subjects could see what their partner was pointing to. The subjects were video-taped during the task.

The Motorcycle Gang Task

The puzzle was almost the same as the original one, except that we used two actual places and replaced the missionaries and cannibals with two teams of motorcycle gangs. The subjects were told to work out how all members of both gangs could be transported safely. This task involved only two kinds of motion: forward and backward motion between two places. The time limit was seven minutes, including the time they used to read the problem sheet.

²Actually, *come* and *go* have more complicated semantics, as shown in Fillmore (1997). The scheme presented here is a rather simplified version, but serves well enough for the present purpose.

³There is one clear difference between English and Japanese, though. When a speaker is trying to go to the hearer, s/he will say, "I'll come to you," while *iku* (go) is used rather than *kuru* (come) in Japanese. However, this difference is not relevant here.

Figure 4: Horizontal and Vertical Diagrams

Experiment 1

The first experiment was conducted to examine the effect of the configurational features of graphics when a perspective based on graphics is taken. The motion in this task was much more simplified, though there was back-and-forth motion that was not in the HCRC Map Task. The problem involved motion between two actual places on a motorbike so that the subject could also directly access the real world. This task has a general direction of motion: all six boys have to move from *Saidaiji* to *Nara*. Each of these locations is about the same distance from the experiment site. The bike was supposed to be able to carry only two people at one time, and someone had to ride back on it. Two kinds of graphical representations were provided as shown in Figure 4. One had a horizontal configuration, in which the two icons of the places are at about the same distance from the subject⁴. The other one had a vertical configuration, which had a variation in the distance from the subject to each place. Each condition had eight pairs of subjects.

The speakers were not supposed to be the ones moving between the two places in this task setting, so the Agent Perspective was not possible. Thus, the possible perspectives were expected to be the Observer-to-World, the Observer-to-Graphic and the Protagonist Perspective. Because the motion is taken as that in the map from the real-world observer in the Observer-to-World Perspective, it is likely that the spatial relation between the speaker and the graphical objects plays an important role. The assumption was that, under that perspective, *kuru*(*come*)-type verbs would be used for the motion to *Nara* more frequently in the vertical condition than in the horizontal one, because they would be affected by the nearness of the *Nara* icon in the diagram to the speaker.

Results of Experiment 1 The distribution of motion verbs was as follows:

Iku-type verbs and *kuru*-type verbs exhibited significantly different distributions depending on the direction of movement in both conditions (horizontal: $\chi^2_{(1)} = 93.64, p < 0.01$; vertical ($\chi^2_{(1)} = 53.98, p < 0.01$). In both the horizontal and vertical conditions, *iku*-type

⁴Note that it is common for maps in Japan to have a direction other than north at the top.

Table 1: Distribution of *iku*-type and *kuru*-type verbs.

		<i>iku</i> -type	<i>kuru</i> -type
Horizontal	Saidaiji → Nara	66	2
	Nara → Saidaiji	4	45
Vertical	Saidaiji → Nara	47	18
	Nara → Saidaiji	1	45

Figure 5: Difference in distribution of motion verbs

verbs were predominantly employed for the movement from Saidaiji to Nara, whereas *kuru*-type verbs were predominantly employed from Nara to Saidaiji. This distributional imbalance indicates that our four perspective types are not sufficient to explain the whole story of graphical communication in problem solving settings, since, for the horizontal condition, movement in each direction could be considered neither toward nor away from the reference point under all four perspectives. Hence one would predict that all movement in the horizontal condition should be expressed with *iku*-type verbs.

We therefore stipulated an additional perspective, the Problem Perspective, to account for this distributional imbalance. As the task for “Missionaries and Cannibals” type problems is to transport all parties collectively from one location to another, the nature of the problem itself induces a general direction of movement from the source location to the goal location. This is equivalent to positing the reference point at the source location, which is Saidaiji in our experimental setting. Under the Problem Perspective each movement is taken as a movement either toward or away from the reference point as posited by the structure of the problem itself, and this perspective is expected to appear in transportation type problems in both concrete and abstract domains.

Comparing the horizontal and the vertical conditions, we notice that *kuru*-type verbs are more frequently used for the movements from Saidaiji to Nara. Figure 5 shows the difference in the distribution of motion verbs between the two conditions. The motion verbs exhibit significantly different distributions between the horizontal and the vertical conditions ($\chi^2_{(3)} = 17.65, p < 0.01$). More concretely, the frequency of the *kuru*-type in Saidaiji to

Nara motion is significantly larger in the vertical condition (adjusted residual: horizontal = -3.87, vertical = 3.87).

The Problem Perspective sets a general reference point at Saidaiji, the source of the whole transportation process. It appears, however, that the graphics configuration may be able to modify the reference point settings. The *kuru*-type showed higher frequency for Saidaiji to Nara in the vertical condition than in the horizontal condition. This shows that the spatial relation between the speaker and the graphical objects makes the transition to the Observer-to-Graphic Perspective, and this affects the reference point setting accordingly. The handiness of the graphical representation can cause a switch in perspectives and thus a shift in the reference point.

In contrast to the increase in *kuru*-type verbs in the vertical condition, we notice no increase in *iku*-type verbs for the movements in the opposite direction. The low frequency of the *iku*-type for Nara to Saidaiji suggests that the perspective switch from the Problem Perspective to the Observer-to-Graphic Perspective is preferred when the resulting perspective takes the movement as a toward movement rather than as an away-from movement. This asymmetry also suggests that the Protagonist Perspective was not playing a significant role, as switching to it would have increased the occurrence of *iku*-type verbs here.

Thus, it was shown that the effect of the Problem Perspective defined by the task was the most prominent factor in reference point setting, but that the configuration of a graphical representation often affects this reference point setting.

Experiment 2

The previous experiment showed that the Problem Perspective was the most influential factor, while the configuration of graphics also affects the usage of motion verbs. Now we will look into the effect of the real-world configuration in conversations involving graphics. The setup of Experiment 2 differs from that of our previous experiment as follows:

- Both of the two conditions had a vertical configuration.
- One of the locations was the current position of the subject (ATR), and the other was a place some distance away.
- One condition was consistent with the physical world, while the other condition was inconsistent with the physical world.

The difference was that one diagram had a configuration consistent with the real-world relationship, while the other did not; that is, the nearer icon in the graphics represented a farther place in the real world. The general starting point was placed at the top of both diagrams. These diagrams are shown in Figure 6.

If the real-world configuration has some effect on setting the reference point, the motion verbs would show

Figure 6: Consistent and inconsistent diagrams

different distributions between the consistent condition and the inconsistent condition. The frequency of *kuru*-type verbs in start-to-goal motion is expected to be lower in the inconsistent condition than in the consistent one. If the real-world configuration did not have much effect, then the distribution would be almost the same between these two conditions. Each condition had eight pairs of subjects.

Results of Experiment 2 The distribution of motion verbs was as shown in Table 2.

Table 2: Distribution of *iku*-type and *kuru*-type verbs in Experiment 2.

		<i>iku</i> -type	<i>kuru</i> -type
Consistent	Start → Goal	70	17
	Goal → Start	1	48
Inconsistent	Start → Goal	47	25
	Goal → Start	4	42

No significant difference was observed between the consistent and inconsistent conditions ($\chi^2_{(3)} = 7.00 < 7.81, p = 0.05$). Furthermore, a comparison of each condition with the vertical condition in Experiment 1 also did not show any significant difference (consistent vs. vertical: $\chi^2_{(3)} = 2.14 < 7.81, p = 0.05$; inconsistent vs. vertical: $\chi^2_{(3)} = 2.83 < 7.81, p = 0.05$). The distribution in each condition was similar to the distribution in the vertical condition of Experiment 1. The *kuru*-type was observed in the Start-to-Goal motion in both conditions. The frequency of the *iku*-type for the Nara to Saidaiji motion was again quite low.

The results show that spatial consistency did not contribute to shifting the reference point. The Observer-to-World Perspective did not have a strong influence in conversation with a diagram. The Protagonist Perspective was also weak in this setting.

It turned out that the spatial property of graphics had a stronger effect on event conceptualization than that of its target world. This suggests that the Observer-to-Graphic Perspective is stronger than the Observer-to-World Per-

spective in graphical communication settings.

Conclusion

We have analyzed the effect of graphics on language usage in communication. Based on an empirical analysis of the uses of movement verbs in actual conversational data, we have shown that the configuration of a graphical representation affects the reference point setting when people conceptualize motion events from graphics-based perspectives. We found that: (1) the task settings provided yet another kind of perspective, the Problem Perspective, setting a general reference point to the general origin; (2) the Problem Perspective is stronger than graphics-based perspectives; (3) the Observer-to-Map Perspective is the next strongest; and (4) the real-world perspective does not contribute, in comparison with the graphics-based perspective, to the reference point shift.

These results suggest that we are mainly grasping an event of the target world via its representation, rather than from the event itself, in graphical communication situations. The point of using graphical representations is the convenience and the ease of access they give us, which helps us to grasp an event through the mediation of graphics. This mediation makes it possible to talk about distal objects by manipulating their proximal counterparts, thereby facilitating both communication and reasoning processes. This provides us with a novel set of perspectives based on graphics, and conceptualization of target events may be affected by the features of the graphics when people rely on those perspectives.

Abstract

In this paper we present a pragmatic analysis of a widely used task in the field of hypothesis testing: the 2-4-6 problem (Wason, 1960). In this task participants have to discover the rule "three increasing numbers" by testing triples of numbers and are given the "2-4-6" as an example of triples compatible with the rule. We argue that most people fail because the givens of the task are conversationally misleading: first because the 2-4-6 is communicated and is thus presumed to be relevant (Sperber & Wilson, 1995) and second because the rule to be discovered is too simple in the context of the task. In a first experiment we showed that providing the triple without communicating it improved performance in the task. In a second experiment we contextually increased the relevance of the rule and observed that people were thus more inclined to discover it.

Introduction

Imagine that you have to discover a rule that generates triples of numbers. Some triples are consistent with the rule and some are not. Now, somebody who knows the rule – a trustworthy person like an experimental psychologist – is telling you that '2-4-6' is a triple that is consistent with the rule. Will you consider this as helpful information or not? Surely, you will and you will also probably think that the experimental psychologist would expect you to regard this triple as helpful in order to succeed in the task. Hence, you will consider that the salient properties conveyed by '2-4-6' (like "evenness" or "increase by 2") must be taken into account in order to discover the rule. However, considering that these properties are important is in fact deceptive since the rule to be discovered does not relate to them: the rule is simply "*three increasing numbers*". Focusing on 2-4-6's most

salient properties is thus not the good way to solve such a task!

This task is the well-known '2-4-6' problem designed by Peter Wason more than forty years ago (Wason, 1960) in order to investigate hypothesis testing ability (see Gorman, 1995 and Poletiek, 2001 for reviews). It has become the most commonly used task by researchers in the field of hypothesis testing. In its standard version, it consists in proposing sequences of triples to discover a rule the experimenter has in mind. For each triple, the experimenter indicates whether or not it is consistent with the rule. Participants have to test triples until they are sure of having discovered the rule. As for the other famous Wason's task, namely the selection task (Wason, 1968), one stimulating aspect of the '2-4-6' problem is that few people succeed in it despite of its apparent simplicity. In the initial study (Wason, 1960), only 21% of participants succeeded in discovering the rule in their first announcement. Typically, the rules proposed by participants inherit the salient properties of '2-4-6' and are more specific than the rule to be discovered. For instance, they propose rules such as "*three even numbers*", "*numbers increasing by 2*", "*even numbers increasing by 2*".

The failure in the 2-4-6 task has often been viewed as a sign of irrationality. Wason argued that participants exhibited a "confirmation" bias, and Evans (1983; 1989) argued that people exhibited a "positivity" bias. The protocols indeed reveal that people tend to propose instances of triples compatible with their hypothesis whereas the most efficient strategy consists of proposing instances inconsistent with the held hypothesis. It is commonly accepted that people overly rely on a positive testing strategy and focus on too narrow hypotheses (Poletiek, 2001). What is the reason for this? Researchers assume that positive testing is

simply a natural way of thinking typical of human beings (Evans, 1989; Klayman, 1995) and that the consideration of restrictive hypotheses is due to the salient properties of 2-4-6. In contrast, we think that the incidence of positive testing and the size of "restrictiveness" bias (Poletiek, 2001) have been overestimated. We believe that one of the most important analysis required for understanding the psychological mechanisms underlying the task has been systematically overlooked, namely the *pragmatic analysis*. In the present paper, we argue that a key cause of the failure in the 2-4-6 problem derives from *communication*. In particular, we claim that the task is difficult precisely because the triple 2-4-6 is obtained by communication.

The pragmatics of the 2-4-6 problem

Nobody can contest that conversation plays an important role in the task. First, like many reasoning tasks, the 2-4-6 problem sets up a situation of communication. The experimenter communicates the givens of a problem to a participant and the participant has to communicate the experimenter a conclusion in order to provide him with some information about his or her inferential skills. The participant tries to determine the experimenter's communicative intention and has some expectations about what he or she is interested in. She or he may thus tailor her/his answer according to these expectations. Second, and more importantly, communication is noticeably misleading in the 2-4-6 problem. In Gricean terms, one can view the experimenter as being uncooperative (Grice, 1975) since the triple he/she intentionally choose is overly specific and does not illustrate the level of generality of the rule. Communicating the triple '2-4-6' to illustrate a typical example of the rule is thus a violation of the second maxim of quantity which stipulates that the speaker should not make his/her contribution more informative than required (Grice, 1975). Of course choosing a triple whose most salient properties are consistent with much more specific rules than the one to be discovered was done in purpose. Wason and other subsequent researchers wanted to see if people were able to come up with general hypotheses by attempting to falsify specific hypotheses drawn from the triple 2-4-6. However, what has been neglected is the fact that the consideration of specific hypotheses is made on the basis of a triple that is communicated. Giving the participant a specific triple has not been seen as a violation of a rule of communication but rather as a way to suggest specific hypotheses. Consequently, researchers have not assessed the impact of misleading communication on weak performance in the task. To which extent does the fact that 2-4-6 is communicated contribute to the restrictiveness bias? In this paper, we aim at investigating this issue.

Our pragmatic analysis of the 2-4-6 relies on relevance theory (Sperber and Wilson, 1995). The concept of relevance is characterized by cognitive effects and cognitive effort, and the degree of relevance relies on these two factors: on one hand, the greater the cognitive effects resulting from processing an information, the more relevant the information; on the other hand, the greater cognitive effort required to achieve these effects and process that information the lesser its relevance. Sperber and Wilson (1995) argue that human communication is governed by a *communicative principle of relevance*. According to this principle, each utterance conveys a presumption of its own relevance. This makes an important difference between information received from a communicator and information not obtained by communication. A communicated information raises expectations of relevance. The communicator manifestly intends the information to be relevant enough to deserve the consideration by the addressee. Presuming that the information is relevant implies first that the effects will be sufficient to offset the effort required to process the communicated information. Second, it implies that the effort required is presumed to be minimal to reach the level of expected effects given the communicator's ability. The presumption of relevance sets up a comprehension strategy, which consists in following a least-effort path: considering cognitive effects in order of accessibility and stopping the processing effort when the level of expected relevance is met.

Let's now turn to the task itself. When the experimenter gives the participant '2-4-6' as an example consistent with the rule to be discovered, this triple is accompanied by a presumption of relevance. In other words, the addressee should presume that this triple is relevant to discover the rule. What type of cognitive effects may the addressee expect to draw from processing the triple? She/He will expect that the triple will look as having been generated by a rule and thus will search for properties common to the three numbers or for properties about the way these numbers are ordered. There are many properties that can be attributed to the 2-4-6 triple, but some of these properties are much more salient (i.e. they immediately come to mind with minimal processing) than others. Given the presumption of relevance, the properties to be considered in order to discover the rule are those that are easily accessible from processing 2-4-6 (for instance "evenness" and "increase by 2").

This does not necessarily mean that the rule should correspond exactly to one or several of the most salient properties but this means that these properties indicate the directions to investigate in order to discover the rule. Actually, the rule may still be quite hard to discover and integrate many other characteristics than the one conveyed by the triple, but what is saliently

given in the triple is relevant to discover it. Hence, because the triple is presumed to be relevant, the most accessible properties it conveys cannot be considered as inappropriate clues to discover the rule. When the experimenter communicates the triple '2-4-6' while he wants the participant to discover the rule "three increasing numbers", he violates the participants' expectations of relevance.

Another cause that may contribute to mislead participants is the rule to be discovered itself. When a person is taking part in a reasoning experiment she/he should normally expect to provide the experimenter with some information about her/his inferential skills. Trivial tasks and trivial answers are not well suited for this: they require little cognitive competency and should not interest the experimenter. In order to provide an answer relevant to the experimenter, the participant will probably expect the task to be of a certain level of difficulty. Faced with a task consisting of discovering a rule about numbers, participants should thus think that this rule should be a bit challenging to discover. However, "increasing numbers" is actually one of the most obvious rules applied to order numbers and in daily life we very often encounter set of numbers sorted according to it. Consequently, participants may be reluctant to think of discovering such an undemanding and widespread rule and may try to achieve relevance by seeking for more difficult rules. As he/she is misleading in communicating the triple, the experimenter is also misleading about his own expectations since he actually expects the participants to find out one of the less relevant (i.e. the simplest) rule to discover in the context of the task.

In our experiments we aimed at showing that misleading participants in their expectations of relevance influence task performance. We used a less deceptive way to convey the givens of the problem while still keeping the same provided example (i.e. 2-4-6) and the same target rule (i.e. increasing numbers). In the first experiment, the presumption of relevance, which accompanies the triple 2-4-6 in the standard version of the task, was removed: 2-4-6 was *given* but *not communicated*. In the second experiment, we increased the relevance of the target rule "three increasing numbers".

Experiment 1

In this experiment, there was no presumption of relevance accompanying the triple 2-4-6 in one of the two conditions. Before receiving the instructions of the rule discovery task, participants had to manipulate a "jackpot" generating triples of numbers at random. After several trials, the experimenter gave the participant the instructions about the rule discovery task. He/She then asked the participant to trigger the jackpot for a last time and told him whether or not the

obtained triple was compatible with the rule. However, the jackpot was biased in such a way that the sequence 2-4-6 came out on this trial. The participant obviously did not know that we rigged the jackpot on this trial and she/he could expect the triple to be consistent or inconsistent with the rule. Hence, from the participant's perspective, the salient properties of the 2-4-6 just result from chance. Even if this triple suggests specific hypotheses, the participant cannot consider them as ones the experimenter necessarily wanted him/her to think about. This because the triple has not been chosen intentionally, in contrast with the standard version of the task. Participants should rely much less on the salient properties of the 2-4-6 and should perform better than in the standard version. We predict that subjects would focus less on the specific properties conveyed by the triple. Consequently, they should test a greater variety of triples: we should thus observe a greater rate of triples increasing in an irregular way (i.e. triples whose numbers do not increase with the same interval, see also Vallée-Tourangeau, Austin & Rankin, 1995) or counterexamples of the rule to be discovered (i.e. triples which are not increasing).

Participants

Fifty-eight undergraduate psychology students from the University of Caen (France) participated in this experiment. They were tested individually.

Procedure and materials

In the control condition (N=29) participants received the task with the standard instructions. They were required to discover a rule the experimenter had in mind by proposing sequences of three numbers and were given '2-4-6' as an example of triples compatible with the rule. To make sure that the participant well understood the instructions, which were printed on an instruction sheet, the experimenter re-explained them and asked the subject if he/she had any questions. Participants kept a written record of the triples they proposed, their hypothesis about the target rule, as well as the experimenter feedback.

In the "jackpot" condition (N=29), participants were faced with a computer screen resembling a jackpot machine. Participants were informed that it randomly generates sequences of three numbers. The experimenter asked the participants to trigger the jackpot by pressing the key "ENTER". After five trials, the experimenter stopped the "jackpot" session. At this point, the participant did not know yet the purpose of the task and did not know what the use of the jackpot was for. After the jackpot session, the participant was given the rule discovery task as in the standard version. However, instead of receiving an example communicated by the experimenter, he/she had to

trigger the jackpot for a last trial. The experimenter would thus tell him/her whether or not the triple supposed to be randomly generated was consistent with the rule. For each participant, the sequence 2-4-6 came out at this trial and the experimenter told the subject that it was consistent with the rule to be discovered. The participant subsequently had to generate triples by herself/himself, like in the standard version. The jackpot was thus not used to generate triples after "2-4-6" was obtained.

Results

Performance As predicted participants performed better in the jackpot condition than in the control condition: Only 24% of participants gave the correct rule on their first announcement in the control condition (21% in Wason's study) while 55% did so in the jackpot condition ($\chi^2(1) = 5.84, p < .02$). Moreover, the mean number of rules announced to reach the correct solution was higher in the control condition than in the jackpot condition (2.38 vs. 1.59; *Mann-Whitney* $U_{29,24} = 214, Z = 2.39, p < .01$); for the five participants of the control group who failed in the task, the mean number of proposed rules was 2.6).

Number and types of triples Participants tested more triples before proposing a rule in the jackpot condition than in the control condition. The mean number of proposed triples per rule by participants who succeeded in the task was higher in the jackpot condition than in the control condition (8.15 vs. 6.11; $U_{29,24} = 202, Z = -2.6, p < .009$). The mean proportion of counter-examples (i.e. triples that received negative feedback) for successful subjects was lower in the control condition than in the jackpot condition (0.17 vs. 0.25; $U_{29,24} = 207.5, Z = -2.51, p < .01$; this rate is equal to 0.06 for the 5 participants who failed in the control condition). Similarly, the mean proportion of irregular increasing triples was lower in the control condition than in the jackpot condition for these subjects (0.18 vs. 0.29; $U_{29,24} = 218, Z = -2.32, p < .02$; this rate is equal to 0.02 for the failing participants). These results indicate that subjects in the jackpot conditions were more prompt to explore a greater variety of triples than subjects in the control condition who focused more on triples exhibiting the salient properties of the 2-4-6.

Discussion

Removing the presumption of relevance of the triple '2-4-6' was helpful: twice as many subjects discovered the correct rule in a single announcement when the triple 2-4-6 was provided without any presumption of relevance and 83% of participants in the jackpot condition succeeded in the task in no more than two announcements. Moreover, even though giving 2-4-6 in

the jackpot condition may still suggest specific hypotheses related to the salient features of this triple, the fact of removing its presumption of relevance entails that these features do not necessarily have to be taken into account in order to succeed in the task. Consequently, participants in the jackpot condition were more inclined to consider alternative properties and thus tested a greater variety of triples than in the control condition.

Experiment 2

In contrast with the Wason selection task literature, in which the content question has led to a vast amount of research, no study has ever investigated content effects with the 2-4-6 problem. That is in the earlier experiments, numbers in the triples proposed by participants or given by the experimenter never referred to real quantities. However, when we use numbers in daily life, we most of the time refer to concrete quantities like books, people, dollars, reasoning errors and so on. We conjectured that framing the task with a real content situation might influence performance. In particular, we think that using an appropriate content and context can enhance the relevance of the rule "three increasing numbers".

In a previous section, we claimed that the rule of increase was too simple to deserve the interest of the participant in the context of an experimental task. However, in real life situations people definitely not avoid looking for an information for the reason that it is too easy to access. They try to look for information that matters for them. We believe that in some contexts, searching for a rule of increase is likely to be cognitively efficient. Indeed, in many real life situations, following a rule of increase is actually highly relevant. A paradigmatic example is economic activity. An economic agent always aims at following such a rule: he or she wants his/her turnover, sailings, productivity, profits, or market scope to increase over the time. Hence, we framed the 2-4-6 task in the context of economic activity. In such a context, the task was to discover not a rule an experimenter – who studies human reasoning and hypothesis testing – had in mind but a rule about car sailings that a garage owner imposes to his new employee. From the participant's perspective, what is relevant for an experimental psychologist who studies cognitive skills is likely to be different from what is relevant for a garage owner. Indeed, searching for the most common way to order numbers (i.e. rule of increase) may be seen as too simple in one case, whereas it becomes highly relevant in the other. Hence, we predict that people will discover the rule "three increasing numbers" more often when the search for such a rule occurs in the context of economic activity.

Participants

One hundred and twenty undergraduate psychology students from the University of Leuven (Belgium) participated in this experiment.

Procedure and materials

The procedure used in this experiment substantially differed from the one we used in Experiment 1. Indeed, participants did not interact with the experimenter. The instructions were given via a computer and participants had to enter the triples they wanted to propose in the computer. The feedback about the triple proceeded in the following way: when the proposed triple was consistent with the rule it appeared in green and when it was inconsistent it appeared in red. The consistent/inconsistent triples remained on the screen where they were presented. After each trial participants had to press the [1] key when they wanted to test another triple, and the [2] key when he/she was sure of having discovered the rule, after which he/she had to type in the rule. After one rule announcement, the experiment ended. This contrasts with Experiment 1 in which participants could propose rules until they discovered the target rule. Participants were tested in groups of ten to twenty people each on their individual computer. In the control condition ($N=62$), participants had to discover a rule implemented by the experimenter in the computer. In the "economic" condition ($N=58$) participants received the following real life context:

"Mister Jansens is a prosperous garage owner. He has recently posted an advertisement in order to recruit a car salesman. Bert answered the ad and obtained an interview with Mr Jansens, he told him that he was very motivated for the job but he also informed Mr Jansens that he never sold any car before. Mr Jansens had a good feeling about Bert, but he thinks that an interview is not enough to decide if Bert will be a good car salesman. Hence, Mr Jansens offers Bert to work in his garage for three months as a sale-training period. If Bert does a good job, then he will decide to hire him. In particular, in order to be recruited, Bert's sales during these three months have to follow a rule required by Mr. Jansens. Bert willingly accepts the proposition.

Three months later... It's time for balance! The first month, Bert has been able to sell 2 cars, the second month 4 cars and the third 6 cars. The verdict of Mr. Jansens is very clear: "Perfect! Your sales have well respected the rule. So, I can hire you!"

Results and discussion

In line with our prediction, more participants discovered the rule in the economic condition than in the control condition (3.2% vs. 29.3%; $\chi^2(1)=15.3$, $p=.0001$). Moreover participants proposed a greater number of triples in the economic condition than in the

control one (2.45 vs. 3.73; *Mann-Whitney* $U_{62,58}=1121.0$, $Z=-3.645$, $p<.05$). This indicates that people abstract more beyond the hypotheses suggested by the 2-4-6 triple and thus tested a greater variety of triples. In particular, the mean proportion of irregular increasing triples was higher in the economic condition than in the control one (.090 vs. .125, *Mann-Whitney* $U_{62,58}=1553.5$, $Z=-1.689$, $p<.05$ one-tailed). The mean rate of counter-examples was also higher in the economic condition than in the control one but this difference was not significant (.10 vs. .12). Hence, the results reveal that increasing the relevance for searching the rule "three increasing numbers" improved performance and thus show that people adapt their cognitive skills in order to maximize relevance (Sperber & Wilson, 1995): on one hand, it is indeed not really relevant for a participant to search for a trivial rule like "increasing numbers" in order to exhibit to a cognitive psychologist her/his own cognitive skills, especially if the experimenter provides an example which does not suggest such a rule; on the other hand, it becomes much more relevant to search for a rule of plain increasing in the context of economic activity.

General discussion

In this study we provided the first extensive conversational analysis of the 2-4-6 problem. We argued that communication was highly misleading in this task and that this explains why people focus on overly narrow hypotheses. We claimed that being misled is not a clue of irrationality. We showed that when participants were not misled, they were not so bad after all. In the standard task, people are misled because they rationally consider that the givens of the problem are relevant to solve the task.

Our experiments aimed at providing less deceptive tasks and show that this increased performance. In Experiment 1, we designed a task in such a way that there was no presumption of relevance accompanying the triple 2-4-6. This implied that the salient properties of the 2-4-6 did not have necessarily to be considered by the participant in order to succeed in the task. The results showed that participants performed better when the salient characteristics of the 2-4-6-triple resulted from a random procedure (a jackpot) than when a presumption of relevance accompanied such a triple (as in communication). In Experiment 2 we manipulated the content of the task: triples did not refer to abstract numbers as it has always been the case in previous studies but to numbers of cars sold within a three months period. We framed the task within the context of economic activity in order to increase the relevance of searching for the rule "three increasing numbers". Our study shows that participants tailor the search of their hypotheses according to what they expect to be relevant in the task. When expectations of relevance

coincide with the correct rule, they are more prone to discover it. This is line with the pragmatic analysis of the Wason selection task made by Sperber, Cara and Girotto (1995). According to them, performance in this task is determined by expectations of relevance. Subjects fail in this task because intuitions of relevance do not coincide with the logical answer. Increasing the rate success consist in constructing a context in which intuitions of relevance will match with the logical answer.

A pragmatic analysis of the conversational structure of a cognitive task may be highly helpful in assessing the quality of participants' skills. There is now an increasing body of research in the domain of high-level cognitive processes revealing that lack of rationality is mistakenly attributed on the basis of misleading tasks (for reviews see, Politzer, 1986; Hilton, 1995; Politzer & Macchi, 2000). These studies as well as ours should alert psychologists that weak performance in a task might be overestimated in the absence of a pragmatic analysis.

Acknowledgements

We are very grateful to Professor D. Trooux and his students of the University Institute of Technology of Caen for the design of the "jackpot" we used in Experiment 1.

Abstract

Literature on relational reasoning mainly focuses on the performance question. It is typically argued that problem difficulty relies on the number of "mental models" compatible with the problem. However, no study has ever investigated the wording of conclusions that participants formulate. In the present work, we analyse the relational terms that people use in drawing conclusions from spatial relation problems (A is to the left of B, B is to the left of C, D is in front of A, E is in front of C, What is the relation between D and E?). We show that the linguistic form of premises, the presentation format, the orientation of the question and the internal inspection of the mental model are important factors in determining the wording of conclusions. Our study shows that the type of conclusion produced provides a key to identifying the mental processes involved in solving these problems.

Introduction

Consider the following relational reasoning problem:

A is to the left of B
B is to the left of C
D is in front of A
E is in front of C
What is the relation between D and E?

How might this problem be solved? One possibility consists of building in one's mind an analogical representation, which exhibits the relation between D and E:

A	B	C
D		E

Another is to use inference rules and apply these rules to the propositional form of the premises to derive the required relation. During the last forty years, numerous studies have attempted to discriminate between these two approaches. In the sixties and seventies, they were respectively labelled the 'analogical' approach (DeSoto, London & Handel, 1965; Huttenlocher, 1968) and the 'linguistic' approach (Clark, 1969a; b) and related to representational processes. In the eighties and nineties, they were labelled the "mental model" (Johnson-Laird, 1983; Byrne & Johnson-Laird, 1989) and the "mental

logic" approaches (Hagert, 1984; Rips, 1994; Braine & O'Brien, 1998) and related to inferential processes.

To compare these two approaches, researchers have relied on performance results (see Evans, Newstead & Byrne, 1993 for review). They either consider the correctness of the conclusion or the response time. However, no study has ever investigated the type of conclusions that people formulate. It is rather surprising that psychologists of reasoning have ignored this question since in another field of deductive reasoning, namely reasoning involving quantifiers like "all", "none", and "some", this issue was one of the first to be investigated under the guise of the 'atmosphere' effect (Woodworth & Sells, 1935). This effect, which has since been extensively explored (see Evans, Newstead and Byrne, 1993 for review) refers to the fact that universal premises (All A are B) prompt universal conclusions, particular premises (Some A are B) prompt particular conclusions, affirmative premises prompt affirmative conclusions and negative premises prompt negative conclusions.

The question we will address is that of the wording of conclusions in relational reasoning. In the above example, the answers "D is to the left of E" and "E is to the right of D" are both correct. But which of these two conclusions do people actually draw? In this article, we want to show that taking into account the wording of the conclusions can reveal several important mechanisms that occur in representing and in reasoning from spatial relational descriptions. We now present several factors that may influence the wording of conclusions.

The linguistic form of the premises

According to mental model theory, there are two stages in representing the premises. The first stage, which is compatible with a linguistic approach, consists of forming a propositional representation that is close to the surface form of the sentence. The second stage consists of using this propositional representation as a basis for constructing a mental model that is analogous to the situation described in the premises. Once the model is built, the linguistic details of the premises and their propositional representation tend to be forgotten (Mani & Johnson-Laird, 1982). The formulation of the

conclusion should then rely only on the mental model, which does not keep track of the comparative expression in the premises. Hence, the comparative used in the premises should not be used more often than its contrary in formulating the conclusion. 'Left-left' problems, whose first two premises contain the comparative 'left' (problems 1-2-9-10 in Table 1a) should not prompt more 'left' conclusions than 'right-right' problems (problems 7-8-15-16 in Table 1b).

On the other hand, according to the linguistic approach (Clark, 1969a; b; Hagert, 1984) the comparative used in the conclusion should be congruent with the comparative used in the premises. In the above example, the first two premises will be represented by two independent propositions: LEFT (A,B); LEFT (B,C). As a result, the predicates used in the inference rule will match those used in the premises: 'LEFT (X,Y) & LEFT (Y,Z) → LEFT (X,Z)'. Hence, the inferred relation between A and C will be stored with the predicate 'left': LEFT (A,C). Since the relation between D and E is identical to that between A and C, the D-E relation will be stored with the same predicate: LEFT (D,E). More generally, 'left-left' problems should prompt more 'left' conclusions than 'right-right' problems.

It also follows from the linguistic approach that the relevance of the premises may affect the wording of the conclusion. Consider Problem 11 from Table 1. The first premise is irrelevant (as for all problems in Table 1b) since it does not have to be taken into account to answer the question: The relation between D and E relies on the relation between A and C, which is explicitly given by the second premise. Hence, the comparative used in the conclusion is likely to be congruent with the comparative used in that premise. Given this assumption, Problems 11 and 12 (irrelevant premise with 'left', relevant premise with 'right') should prompt more 'right' conclusions than Problems 13 and 14 (irrelevant premise with 'right', relevant premise with 'left').

Table 1: The 16 spatial problems

Table 1a: One-model problems

Pb1	Pb2	Pb3	Pb4
A left B	A left B	A left B	A left B
B left C	B left C	C right B	C right B
D front A	E front C	D front A	E front C
E front C	D front A	E front C	D front A
Pb5	Pb6	Pb7	Pb8
B right A	B right A	B right A	B right A
B left C	B left C	C right B	C right B
D front A	E front C	D front A	E front C
E front C	D front A	E front C	D front A

Table 1b: Two-model problems (first premise always irrelevant)

Pb9	Pb10	Pb11	Pb12
A left B	A left B	A left B	A left B
A left C	A left C	C right A	C right A
D front A	E front C	D front A	E front C
E front C	D front A	E front C	D front A
Pb13	Pb14	Pb15	Pb16
B right A	B right A	B right A	B right A
A left C	A left C	C right A	C right A
D front A	E front C	D front A	E front C
E front C	D front A	E front C	D front A

Problem difficulty and presentation format

Most researchers currently agree that the difficulty of a relational reasoning problem is a function of the number of models it supports. For instance, the following problem,

A is to the left of B
A is to the left of C
D is in front of A
E is in front of C,
What is the relation between D and E?

is compatible with two models,

A	B	C	A	C	B
D		E		D	E

and is more difficult than a one-model problem since two models are harder to construct and store than a single one (Byrne & Johnson-Laird, 1989). It has also been shown that when the number of models increases, people are less likely to construct such models and are more prone to stay at the propositional level of representation (Mani & Johnson-Laird, 1982). Mani and Johnson-Laird argued that the indeterminacy introduced by multiple-model problems disrupts the model construction process. They showed that people were more likely to recall linguistic details for indeterminate than for determinate descriptions. Hence, the premises may have a stronger influence over the wording of conclusions for two-model problems than for one-model problems: The comparative used in the conclusion should be more often congruent with the comparative used in the premises with two-model problems than with one-model problems.

In addition, the presentation format might have an effect on the type of representation involved (see Potts & Scholz, 1975; Ormrod, 1979; Schaeken & Johnson-Laird, 2000; Roberts, 2000) and, consequently, on the type of conclusion formulated. One can distinguish between two ways of presenting the premises. With simultaneous presentation, all premises are presented together

with the question and remain available when one solves the problem. Sequential presentation places more load on working memory: the premises are presented one after the other and disappear each time a new premise or the question occurs. It has been argued (Ormrod, 1979) that an analogical representation is more likely to occur with a sequential presentation. The reason is that in a linguistic representation, each relation – given in the premises or inferred from them – is stored separately whereas in a model representation, all premises are integrated within a single representational format. Thus, when working memory load increases it becomes harder to keep track of the premises and inferences separately and a mental model becomes a more efficient and concise mode of representation. Hence, we should observe fewer conclusions with a relational comparative congruent with that of the premises in the sequential presentation than in the simultaneous presentation.

Scanning the mental model

The wording of the conclusions might reveal how individuals scan the model they constructed. If people scan their model in a 'left-to-right' direction, they will be likely to make a 'left' conclusion since the first element they encounter, which is likely to be the first element mentioned in the conclusion, is on the left part of the model; alternatively, if people scan their model in a 'right-to-left' direction, they will be likely to make a 'right' conclusion. One might suppose that the direction of scanning is driven by left-to-right reading habits (Cicirelli, 1977), leading to 'left-to-right' inspections of mental models and to 'left' conclusions.

Another factor that might govern the direction of model-inspection is the question. The question given in the above examples ("What is the relation between D and E?") initially directs attention to the left side of the models since D is mentioned first in the question and is located on the models' left side. Consequently, such a question is likely to induce a 'left-to-right' inspection of the model and a 'left' conclusion. Inversely, the question "What is the relation between E and D?" is likely to induce a 'right' conclusion.

Finally, the order in which the items are inserted within the model might direct inspection of the model. If the premise containing the D item is provided before the premise containing the E item, D will be inserted before E in the model and the construction of the D-E line will proceed from left to right (granted that D is to the left of E as in all the problems of Table 1). Payne (1993) has shown that people keep track of the construction process. One can extend this approach and assume that keeping track of the construction process may induce people to scan their model in the direction of its construction.

Experiment

Before describing the method of the experiment let us first recall the predictions:

- The linguistic form of the premises should influence the wording of the conclusion according to a linguistic approach but not according to an analogical approach.
- Problems conveying an indeterminacy (i.e. two-model problems) could favor more the occurrence of linguistic processes than determinate problems (i.e. one-model problem).
- A sequential presentation could favor more the occurrence of analogical processes than a simultaneous presentation.
- 'Left-to-right' reading habits could prompt 'left-to-right' inspections of mental models.
- 'Left-to-right' questions could prompt 'left-to-right' inspections of mental models.
- 'Left-to-right' constructions of mental models could prompt 'Left-to-right' inspections of mental models.

Method

Participants The participants were 174 first-year psychology students from the University of Leuven.

Design Each participant received 16 relational reasoning problems (Table 1). Half of these problems were one-model problems (Table 1a) and the other half two-model problems (Table 1b). In half of the problems, the first two premises had the same relational term (four 'left-left' problems and four 'right-right' problems); in the remaining half, the first two premises had different relational terms (four 'left-right' problems and four 'right-left' problems). Moreover for half of the problems (Type-1 problems), the premise introducing the item located on the left (i.e. the item D) was given before the premise introducing the item located on the right (i.e. the item E; Problems 1-3-5-7-9-11-13-15 in Table 1). For the other half (Type-2 problems), this presentation order was reversed (Problems 2-4-6-8-10-12-14-16).

There were two between-participant manipulations: 2 types of presentation format \times 2 types of question. First, participants received the premises and question in a simultaneous presentation format or in a sequential presentation format. Second, the first item mentioned in the question was either the item mentioned in the third premise (i.e. "what is the relation between D and E?" for Type-1 problems and "what is the relation between E and D?" for Type-2 problems) or the item mentioned in the fourth premise (i.e. "what is the relation between E and D?" for Type-1 problems or "what is the relation between D and E?" for Type-2 problems).

Procedure and Materials. Participants were tested in groups of 12 to 20 individuals. The instructions

and the problems were given in Dutch and were displayed on a screen via a data projector. Participants received 2 training problems and 16 randomly ordered test problems with contents relating to fruits and vegetables (see Table 1). In the simultaneous conditions, each problem was displayed for 50 seconds. In the sequential conditions, each premise and the question appeared for 10 seconds. Participants wrote their answers on a sheet of paper.

Results. Performance was in line with the relational reasoning literature since one-model problems were easier to solve than two-model problems (83% vs. 73%, Wilcoxon's $T = 1787$, $n = 131$, $p < .00001$). We now turn to the analysis of the conclusions that people expressed. We discarded incorrect answers and 0.1% of correct but imprecise answers (i.e. 'D is next to E'). We will now discuss the relevant main effects and interactions.

First, participants had a clear preference for 'left' conclusions. Overall, there were 68.6% of 'left' conclusions and 31.4% of 'right' conclusions, suggesting a tendency for mental models to be scanned in a 'left-to-right' direction.

Second, the type of question influenced the wording of the conclusion. With 'left-to-right' questions (D-E?) there were 83.1% of 'left' conclusions (and consequently 16.9% of 'right' conclusions) whereas with 'right-to-left' questions (E-D?) there were only 54.2% of 'left' conclusions (Wilcoxon's $T = 1082$, $n = 135$, $p < .00001$).

Third, the extent to which the question influenced the incidence of 'left' and 'right' conclusions depended on presentation format. Given the 'left-to-right' question, which prompted a 'left-to-right' inspection of the model, simultaneous presentation gave rise to 78.5% of 'left' conclusion while sequential presentation led to 88.5% of 'left' conclusions (Mann-Whitney U 's = 3029.5, $n_1 = 92$, $n_2 = 82$, $p < .01$). A similar, but non-significant trend was obtained for the 'right-to-left' question, which prompted a 'right-to-left' inspection of the model. Here, simultaneous presentation gave rise to 57% of 'left' conclusions, but sequential presentation resulted in 50.7% of 'left' conclusions. The directional scanning induced by the question is apparently enhanced by sequential presentation, in accordance with the notion that analogical processes are more likely under such conditions.

Fourth, the wording of the premises influenced the wording of the conclusions in the simultaneous condition since 'left-left' problems elicited more 'left' conclusions than 'right-right' problems. Whereas, 75.5% of 'left' conclusions were observed for 'left-left' problems, there were 57.4% of 'left' conclusions for 'right-right' problems (Wilcoxon's $T = 385.5$, $n = 61$, $p < .00005$). In contrast, in the sequential condition there was no influence of the linguistic form of the premises since the rate of 'left' conclusions was essentially the same in each type of problem (71.5% for 'left-left' problems, and 71.1% for 'right-right' problems). This

indicates that when the premises were not available, participants were not inclined to use the comparative introduced by the premises. The results suggest that participants tend to adopt a linguistic representation given simultaneous presentation and an analogical representation given sequential presentation.

Similarly, in the simultaneous presentation condition, the findings obtained for two-model problems, which all had an irrelevant first premise, indicated that participants were prone to formulating conclusions congruent with the relevant premise. When the relevant premise contained the comparative 'left' and the irrelevant one contained the comparative 'right', 77.9% of 'left' conclusions occurred; when the relevant premise contained the comparative 'right' and the irrelevant one contained the comparative 'left', 57.4% of 'left' conclusions occurred (Wilcoxon's $T = 236$, $n = 49$, $p < .0001$). However, given sequential presentation, participants were not really inclined to formulate a conclusion congruent with the relevant premise. When the relevant premise contained the comparative 'left', 69.1% of conclusions were 'left' and when it contained the comparative 'right', the percentage of 'left' conclusions was 67.6.

Fifth, one might have expected that when the insertion of the last two items in the mental model proceeds from left to right (Type-1 problems), more 'left-to-right' inspections and 'left' conclusions would occur than when it proceeds from right to left (Type-2 problems). This was not the case and the results even show a tendency in the opposite direction. There were 66.6% of 'left' conclusions for Type-1 problems and 71% of 'left' conclusions for Type-2 problems.

Sixth, it could be argued that when the number of models increases participants should be more prone to relying on the linguistic form of the premises. However, the differences in 'left' and 'right' conclusions were almost identical in one and two-model problems. Indeed, 'left-left' one-model problems gave rise to 73.9% of 'left' conclusions and 'left-left' two-model problems gave rise 73.6% of left conclusions. Similarly, 'right-right' one-model problems gave rise to 62.6% of 'left', and 'right-right' two-model problems gave rise to 64.9% of 'left' conclusions. Hence, people who gave a correct answer to two-model problems did not rely more on the linguistic form of the premises than in the case of one-model problems.

General discussion

Our study is the first to analyze the wording of the conclusions people draw in relational reasoning. We have shown that the wording of conclusions exposes several psychological mechanisms. Two of the effects we have demonstrated are compatible with the analogical approach to reasoning and provide new insight in the way people inspect their

mental model: First, the preference for 'left' conclusions is nicely explained by the fact that people construct mental models and inspect them from left to right. Second, the nature of the question is an important factor in determining the direction of model inspection: a 'left-to-right' question prompts 'left-to-right' inspection of the model and a 'left' conclusion. On the other hand, the congruence effect is compatible with the linguistic approach to reasoning. It shows that linguistic details of the premises, like the type of comparative, are stored in memory and are used in the inferential phase.

However, the occurrence of analogical and linguistic processes and the degree to which they are involved largely depend upon the presentation format. Sequential presentation increases the incidence of analogical processing: the "preference-for-left"-effect and the question-effect were stronger in the sequential condition than in the simultaneous condition. Simultaneous presentation induces linguistic processes: the congruence effect was present in the simultaneous condition but not in the sequential condition.

Interestingly, two effects were not observed. First, the number of models did not influence the wording of conclusions: the congruence effect was not greater in indeterminate problems. At first sight this seems to contradict the results of Mani & Johnson-Laird (1982), who found that people more often recalled linguistic details when the description was indeterminate. But they also reported that recall of the gist was lower when the description was indeterminate. Hence, having a weak representation of the gist of the description was related to high retention of the linguistic details of the sentences supporting the description. However, in the results taken into account here the representation was not weak since only correct conclusions were considered. This might explain the absence of a greater congruence effect with 2-model problems, and shows that when the representation of the description is correct people do not rely more on the linguistic level given indeterminate vs. determinate problems.

Second, the direction of model inspection was not congruent with the direction of model construction. People did not scan their model in the direction they constructed it. When construction of the D-E part of the model proceeded from left to right, it did not prompt more frequent 'left-to-right' inspection than when it proceeded from right to left.

In conclusion, some of the data presented here support the analogical framework and others support the linguistic framework. This contrasts with many reasoning experiments in which the data are considered to be entirely compatible with one approach and entirely incompatible with the other (see also Roberts, 1993).

Our findings show that both linguistic and analogical processes do contribute to the wording of conclusions in spatial reasoning. However, the impact of the different kind of processes is unequal: whereas the simultaneous presentation format provides evidence supporting both approaches (i.e. the congruence effect

and effects related to model scanning were observed), the sequential presentation condition provides empirical evidence supporting the analogical approach and not the linguistic approach (i.e. the congruence effect was not observed for this condition). This pattern of data seems to indicate that analogical processes are pre-eminent in reasoning from spatial premises.

However, a comprehensive theoretical account of these results has to take into account both types of processes. Such a mixed model has been adopted previously by several researchers like Shaver, Pierson & Lang, (1974) Sternberg (1980) and Johnson-Laird (1983; Mani & Johnson-Laird, 1982). According to Sternberg and Johnson-Laird, the premises are first decoded into a linguistic format and are subsequently represented by a spatial mental model. However, this view concerns only the representational phase but not the inferential phase. Accordingly, it seems then that the inferential phase, during which the reasoner produces a conclusion, relies only on the inspection of the mental model. However the data we obtained indicate that the formulation of a conclusion is influenced by both analogical and linguistic factors in the simultaneous presentation, and support the idea that both factors influence not only the representational phase but also the inferential one. A possible explanation is that when people have achieved the construction of the mental model, they go back to the premises, when they are available, and use the premises as a guide to inspect the mental model. According to this view, linguistic factors play a role, but it does not necessarily imply that inferences rules are used while our data clearly indicate that mental models are constructed.

Abstract

This article presents a taxonomic system for generated disablers (based on Elio, 1998) and generated alternatives. Based on the taxonomy, we distinguish three different types of knowledge that are advocated during generation tasks (1) situations that are semantically strongly related to the content of the premises (2) more remote situations and (3) the invalid or low quality counterexamples. Second, we look at the effect of working memory capacity on the nature of generated counterexamples. We found that participants with a high working memory capacity can generate more counterexamples and are flexible in their search process. Participants with low working memory generate less counterexamples and restrict themselves to the first type of counterexamples.

Introduction

Deductive reasoning with causal propositions is one of the core activities of human cognition. The prototypical causal rule is formulated as an 'if-then' sentence. The if-part of the conditional expresses the cause and the then-part contains the effect. The four reasoning problems that are traditionally used to investigate causal reasoning are (1) modus ponens - MP: does the effect follow when the cause is present (2) denial of the antecedent - DA: does the effect follow in absence of the cause (3) affirmation of the consequent - AC: did the cause occur when the effect is observed (4) modus tollens - MT: did the cause occur although the effect did not occur. The answers participants produce to these problems are classically discussed in terms of conditional answers. Schematically, the reasoning problems and answers look as follows. The conditional sentence is: 'If cause, then effect'

	Categorical premise	Conditional answer
MP	The cause occurs.	The effect follows.
DA	The cause does not occur.	The effect does not follow.
AC	The effect occurs.	The cause preceded.
MT	The effect does not occur	The cause did not precede.

Cummins (Cummins, Lubart, Alksnis, & Rist, 1991; Cummins, 1995) found that the tendency to deduce AC and DA is related to the number of alternative causes the reasoner can activate from background knowledge. The number of disabling conditions, on its turn influences the making of MP and MT. Alternative causes is a cause other than the one given, that is capable of evoking the effect. Disabling conditions is an event that can prevent an effect from occurring in the presence of the given cause.

For each of these four reasoning problems Markovits (2000) gives a detailed description of the underlying cognitive mechanism. His theory is based on the mental model theory (Johnson-Laird, 1983; Johnson-Laird & Byrne, 1991). The mental model theory assumes that reasoners build internal models representing the premise content, and through manipulation and extension of these models they generate a conclusion. We will briefly discuss Markovits' (2000) account of how the four reasoning problems are solved (applied to causal reasoning).

The mental model theory assumes that (1) reasoners start by representing the content of the conditional sentence in an economical way, for instance 'cause \rightarrow effect'. This model represents a possible situation and is often called the initial model. Other possible models of situations are left implicit. When they are asked what follows from the categorical premise reasoners verify whether they can produce a conclusion based on the initial model. In case of MP they can initially conclude that the effect occurs, and for the AC they can conclude that the cause preceded. For the other two reasoning forms, there is no explicit information regarding the absence of effect or cause, so no conclusion can initially be generated. (2) In case of DA and MT, reasoners create explicit models of other possible situations. According to Markovits (2000) the preferred second model is 'no cause \rightarrow no effect'. Based on this extra model it is possible to generate an initial conclusion for DA (the effect does not follow) and for MT (the cause did not precede). At this point, a first conclusion is formulated for all four reasoning problems; this conclusion corresponds to the conditional answer. (3) Most reasoners will then validate their initial conclusion by searching for possible counterexamples. For MP and MT, the falsifying model is 'cause \rightarrow no effect' (disabler). For AC and DA, the falsifying situation is 'no cause \rightarrow effect' (alternative). If a counterexample is found, reasoners become aware that there is more than one conclusion possible, and reject the initial conclusion. When no counterexamples are found, reasoners give conditional answers to all four reasoning forms. Hence, the probability of finding counterexamples informs us about the probability of giving conditional answers.

The probability that reasoners find a counterexample depends on the number of counterexamples that are present in semantic memory. When there are many counterexamples, the probability of retrieving at least one is higher than when there are only few counterexamples. In order to check how many counterexamples reasoners can retrace from memory,

researchers ask participants to generate possible alternatives and/or disablers for a conditional sentence. The number of counterexamples generated in this way reflects the number of counterexamples present in background knowledge, thus reflecting the probability that reasoners find at least one counterexample during reasoning.

Previous research has focussed on specific characteristics of generated counterexamples: the absolute number of counterexamples (see e.g., Cummins et al., 1991; Cummins, 1995), the salience of counterexamples (Markovits, 2000), and the strength of association between (alternate) causes and a consequent (Quinn & Markovits, 1998). For disablers, Chan and Chua (1994) and De Neys, Schaeken & d'Ydewalle (2001) described the importance of the perceived strength of the connection between cause and effect. Dieussaert, Schaeken, & d'Ydewalle (2002) investigated the differential effect of disablers referring to the item itself or to speaker control.

Another important characteristic is the type of the generated counterexamples. It is possible that some counterexamples are considered to be of greater importance regarding their falsifying strength, than others are. A first step in this research domain is to develop a taxonomy, which enables us to distinguish different types of disablers and alternatives. Elio (1998) has proposed a taxonomy of 'disablers'. Although she constructed this taxonomy from the perspective of belief revision, we consider this taxonomy also useful for research on 'deductive' conditional reasoning. Elio (2001) herself points out that both research areas are complementary, as 'endorsement and entrenchment of a conditional are opposite sides of the same coin'. No taxonomy has been lined out for alternatives. Developing a taxonomy for alternatives will be the first aim of the present study.

Furthermore, we presume that the ability of generating counterexamples is influenced by working memory capacity. Retrieving a counterexample is considered to be a semantic search process (Markovits, Fleury, Quinn & Venet, 1998) and since the efficiency of a semantic search process is linked to working memory capacity (Rosen & Engle, 1997) we deduce that the retrieving of counterexamples is linked to working memory capacity (see also De Neys, et al., 2002). The present study will provide some preliminary data on this topic. Secondly, we will investigate whether there are differences in the nature of generated counterexamples corresponding to differences in working memory capacity.

TAXONOMY

Disablers

Elio (1998) proposed her taxonomy for disablers in the context of belief-change. She first induced a belief-state about the rule by presenting an MP problem and its conditional answer. Then, the participant finds out that this stated conclusion is contradicted by observed facts and is asked to give some sort of rationalisation. Elio (1998; 2002) distinguishes seven categories of disablers. We will illustrate these categories for the sentence: *'If a plant is watered well,*

the plant stays green'. A disabler for this sentence explains why the plant doesn't stay green although it is watered well.

The first category contains the '*real*' disablers (1), e.g. 'there is no sunlight'. These answers state that normally the cause produces the effect but in the situation under description there is an extra condition present which prevents the effect from occurring. Instances of the second category, *demote to default* (2) merely indicate that the given rule is probabilistic in nature, e.g., 'in most cases the plant stays green, but there are exceptions'. The next category contains the *missing enablers* (3), e.g., 'the plant received too little water'. These responses indicate that a condition necessary for the cause to take effect is absent. The fourth category holds *generalisations* (4) of the effect, e.g., 'the plant stays healthy'. The rationale behind this kind of disabler is that the cause produces an effect, but not specifically the effect mentioned in the rule. Another category contains responses that indicate an *invalid relation* (5) between cause and effect; e.g., 'water is not enough for the plant to stay green'. The sixth category contains *exceptional instances* (6), e.g., 'the plant is an oak with brownish leaves'. The rule remains valid, but the participants lists an instance to which the rule exceptionally doesn't apply. The last category contains answers which make reference to *intervening variables or the passage of time* (7), e.g., 'the plant was watered well until last month'. These responses indicate that the cause was indeed followed by the effect, but something happened that cancelled the effect.

Alternatives

In line with the categories proposed by Elio for disablers, we can construct a taxonomy for alternatives. We will use the same sentence to illustrate the different types of alternative causes, *'If a plant is watered well, the plant will stay green'*. An alternative explains why the plant stays green, even when he is not watered well.

A first category contains the '*real*' alternatives (1), e.g., 'the plant receives a lot of fertilizer'. These are causes, which can also produce the effect, even when the given cause is absent. The second category is called *demote to default* (2), e.g., 'normally the plant needs water to stay green, but not always'. This category contains answers that point out that normally the cause produces the effect, but there are some exceptions, which are not explicitly mentioned. The third category contains *non-missing enablers* (3), e.g., 'the plant needs practically no water'. This category mirrors the missing-enabler category of the disabler taxonomy. The fact that the plant does not need a lot of water is no cause of the plant staying green. It just enables the effect to occur even if the required cause is absent. A fourth category contains the *generalizations* (4), e.g., 'if you take good care of a plant, the plant stays green'. Watering a plant well is an instantiation of the superordinate category 'taking good care of a plant'. The fifth category is the *invalid rule* (5); e.g., 'a plant does not need water to stay green'. This 'alternative' cancels the stated relation between antecedent and consequent. The sixth category contains the *exceptional instances* (6), e.g., 'the plant is a Mexican cactus'. Instances of this category point out that the conditional sentence is valid, but for this

particular example of a plant, the rule does not apply. Finally, the seventh category contains alternatives referring to intervening variables or passage of time (7), e.g., 'after a while the plant learned to live on little water'.

In addition to these 7 parallel categories, we distinguish three extra categories. The first extra category contains answers referring to luck or magic (8), e.g., 'Harry Potter came by and the plant turned green'. The second category contains answers for which the conditional sentence is read in its non-literal meaning (9), e.g., 'the plant sees that other plants receive water and turns green with envy'. A last category is reserved for invalid answers (10), e.g., 'the plant stays green by its photosynthesis', 'the plant does yoga', ... In most experiments where participants are asked to generate disablers or alternatives, these answers are excluded from the analysis. From the perspective of building a taxonomic system, we preferred to put them in a special category. As with Elio's (1998) taxonomy for disablers, we assume that some of these categories have fuzzy boundaries. The category 'luck or magic' is related to 'demote-to-default' and 'exceptional instances'.

The extra three categories are also valid for disablers. They cannot be reduced to one of the seven categories Elio proposed, so for sake of completeness, we will add them to her taxonomy. Since the taxonomy for disablers then fully parallels the taxonomy for alternatives, we can compare the distribution of the answers.

Overall, for disablers as well as for alternatives, we can say that the categories labeled 'disablers' and 'alternatives' contain the 'real' counterexamples. Instantiations of this category appear to be semantically closely related to the content of the premises. The categories 'demote to default', '(non)missing enabler', 'generalization', 'invalid rule', 'time' and 'exceptional instance' are more remote. They either refer to exceptional situations or some of the basic assumptions of the conditional sentence are denied. The categories of 'luck or magic', 'non-literal interpretation' and 'invalid answers' contain counterexamples that can be given to any kind of sentence, regardless of the exact semantic content. We consider these counterexamples to be of *low quality*.

Experiment

Applying the Taxonomy

First of all, we will apply the two taxonomic systems on generated counterexamples. This way we can get some indication of which type background knowledge participants use when asked to produce counterexamples.

Method We used twenty causal 'if-then'-sentences. The sentences covered a broad range of semantic domains. Based on previous research we choose an equal proportion of sentences for the four categories: (1) many disablers and many alternatives, (2) many disablers, few alternatives, (3) few disablers, many alternatives, and (4) few disablers and few alternatives. Our generation task was similar to the one used by Cummins (1995). First, we presented the participants with a causal rule. Subsequently we stated that the cause

occurred but it did not produce the effect (disablers) or that the effect occurred in absence of the given cause (alternatives). Participants were then asked to write down as many explanations as possible (maximum 5). It was explicitly mentioned that the given explanations had to be different from the stated cause, different from each other, and that they could only give valid answers, answers such as 'the person came from Mars' are not tolerated.

Sixty-two subjects participated in the experiment as part of course requirements. Thirty-two subjects were given the disabler-generation task, while thirty other subjects received the alternative-generation task. Each participant generated either disablers or alternatives for each of the 20 sentences. The order of the sentences was randomized over participants. The participants were given 15 to 20 minutes to complete the task. For each situation that participants generated, two independent raters determined to which category type the answer belonged. Interrater reliability was .93 for the alternative and .84 for the disabler generation task.

Results and Discussion Both for the alternative and disabler generation task we first divided the sentences into two groups. For one group of sentences ($n=10$) there are few alternatives or disablers (dis/alt) generated, while in the other group ($n=10$) there are many dis/alt. The few-group contains sentences for which the total number of generated counterexamples for the sentence is less than the overall mean of all sentences. For the sentences of the many group the number of generated counterexamples for each sentence is higher than the overall mean.

For the alternatives as well as for the disablers, we determined the number of times each category type occurred, this separately for the few and the many sentences. Table 1 gives an overview of the results.

Table 1: Proportion of answers for different categories.

Category	Disablers		Alternatives	
	Few	Many	Few	Many
1. real alt/dis	76.8	81.9	74	94.5
2. demote to default	0.6	3.1	3.6	1.5
3. (non)missing enabler	12.4	7.1	1.9	-
4. generalization	0.6	2.2	2.1	3
5. invalid rule	-	-	-	-
6. exceptional instance	4.1	3.6	10.6	0.1
7. time/ intervening	3.6	1	0.4	-
8. luck/magic	-	0.8	3	0.2
9. non-literal	-	-	0.4	-
10. invalid	1.9	0.2	3.8	0.6
Total N	531	869	470	976

Within the many-group there are relatively more 'real' dis/alt generated than in the few-group. This difference is significant for disablers ($p_1=.768$, $n_1=531$ versus $p_2=.819$, $n_1=869$, $p<.0209$) as well as for alternatives ($p_1=.74$; $n_1=470$ versus $p_2=.945$, $n_1=976$, $p<.0001$). Additionally, we found that for the few disabler group, more missing enablers are generated than for the many group (dis: $p_1=.124$, $n_1=531$ vs. $p_2=.071$, $n_1=869$, $p=.0008$). For alternatives we observe that

in the few group participants more often list exceptional instances than in the many group ($p_1=.106$, $n_1=470$ vs. $p_2=.01$, $n_1=976$, $p<.0001$). All other differences between proportions are non-significant.

We assume that when participants are asked to generate dis/alts they start to look for straightforward examples, namely the 'real' dis/alts (category 1). This is because the 'real' counterexamples are semantically strongly related to the content of the conditional sentence. In addition to these 'real counterexamples' participants dispose of another pool of possible counterexamples, namely, the more remote situations. Instantiations of this type are semantically not directly linked to the premise content. They refer to exceptions to the normal situation (category 2,6) or to conversational implicatures that are suspended (category 3,4,7). The assumptions that are normally valid, such as 'promises are kept', 'birds can fly', 'coffee contains caffeine' are examined in order to account for the apparent contradicting premises. In general, this more remote category contains counterexamples sprouting from suspended conversational implicatures (Levinson, 2000).

For some assumptions you find that when the assumption not holds, the relation between antecedent and consequent changes, and can account for the apparent contradiction.

When only few dis/alt can be found, it is harder to find a full range of 'real' counterexamples. As a result, participants search also for the more remote type of disablers and alternatives.

Conclusion The two taxonomic systems can be used to categorize the answers participants give when asked to generate disablers or alternatives. Although some of the presented categories are conceptually related, the raters consistently classified the answers.

By applying the taxonomy we found that more 'real' alternatives and disablers were generated in the many groups than in the few groups. This difference is compensated by a shift to the more remote types. We assume that participants start searching for counterexamples from the pool of 'real' counterexamples, because these counterexamples are

semantically close to the content of the premises. In addition, the search can be directed to the more remote categories.

In the second part of this experiment we will investigate whether working memory capacity affects the type of the generated dis/alts.

Working Memory Capacity

Double task experiments showed that working memory capacity puts a constraint on the ability to generate counterexamples (De Neys, Schaeken, & d'Ydewalle, 2002). First, we will investigate the effect of working memory capacity on the *number* of generated counterexamples. We expect that participants with high working memory capacity generate more counterexamples than those with low working memory capacity. We expect this difference to be larger for sentences with few counterexamples. For the many sentences we assume that the difference may be blurred due to a ceiling effect. Second, we will look at the effect of working memory on the *type* of generated counterexamples. Do differences in working memory capacity affect somehow the sort of counterexamples participants come up with?

All first year psychology students had fulfilled a Dutch version of the OSPAN test (La Pointe, & Engle, 1990; Dutch version: De Neys et al., 2002) for measuring working memory capacity. As such, we can link the number and nature of the generated answers to differences in working memory capacity.

Results and Discussion The subjects are divided in three groups depending on their working memory capacity. The high participant group consists of the top third (dis: Min: 37; Max: 54 - alt: Min: 39; Max: 54). The low group contains participants with scores of the bottom third (dis: Min: 18; Max: 24 - alt: Min: 39; Max: 54). Table 2 displays the distribution of the relative proportion of answers.

Participants with high working memory capacity generate more disablers than participants with a low working memory capacity (dis: $p_1=.45$; $n_1=964$ versus $p_2=.55$; $n_1=964$, $p<.0001$). This difference is not significant for alternatives.

Table 2: Proportion of generated counterexamples for each category (numbers refer to categories of Table 1). The shaded regions refer to the three types category 1 equals Type 1, category 2 to 7 corresponds to Type 2, categories 8 to 10 are labeled Type 3.

Category	Disablers						Alternatives					
	Low			High			Low			High		
	Few	Many	Total	Few	Many	Total	Few	Many	Total	Few	Many	Total
1	82.5	86.4	85	71.7	80.1	76.7	79.4	95.2	90.4	76.7	93	87.7
2	5.8	2.9	3.9	0.9	4.2	2.8	6.1	1	2.6	2.8	1.5	1.8
3	3.9	5.7	5.1	14.6	8.7	11.1	1.8	-	0.6	4.4	-	0.5
4	0.6	1.4	1	0.5	2.9	1.9	-	3.2	2.2	1.1	3.5	2.7
5	-	-	-	-	-	-	-	-	-	0.6	-	0.2
6	3.3	2.5	2.8	5	2.6	3.6	5.5	0.3	1.9	8.9	-	2.9
7	3.3	-	1.2	3.7	0.6	1.9	0.6	-	0.2	-	-	-
8	-	1	0.7	-	0.6	0.4	4.2	-	1.3	2.8	0.5	1.3
9	-	-	-	-	-	-	-	-	-	0.6	0.3	0.4
10	0.6	-	0.2	3.7	0.3	1.7	2.4	0.3	0.9	5	1.5	2.5
Total N	154	279	433	219	312	531	165	375	540	180	371	551

We will now discuss the effects of working memory capacity separately for the sentences with few and many disablers.

A first important result is that the observation that participants with high working memory capacity generate *more disablers* than those with low working memory capacity, is only found on the sentences with few disablers ($p_1=.413$; $n_1=373$ vs. $p_2=.587$; $n_2=373$, $p<.0001$). This finding can be explained as follows. For sentences with only few disablers, it is inevitably harder to generate counterexamples than for sentences with many disablers. In general, for sentences with only few disablers most participants quickly run out of inspiration (only in 5% of the trials there were more than 3 disablers given). Because participants with low working memory capacity experience more difficulty in generating disablers, we can expect that their searching process takes more time than that of participants with high working memory capacity. For sentences with many disablers, we assume that there is a ceiling effect. As participants can choose from a large pool of possible counterexamples, the differences in working memory capacity on the generated number of counterexamples does not show.

A second striking finding is that participants with a low working memory seem to restrict themselves to a single type of counterexamples. Participants with a high working memory capacity generate overall more 'real' disablers, this group represents a larger proportion of the generated responses of the participants with low working memory ($p_1=.85$; $n_1=433$ vs. $p_2=.77$; $n_2=531$, $p<.0013$). This decrease in 'real' disablers is mirrored by a significant increase in the proportion of disablers of the 'remote' type. Participants with a high working memory score generate more missing enablers (category 3) than participants with low working memory capacity ($p_1=.051$, $n_1=433$ versus $p_2=.111$, $n_2=531$, $p<.0009$). As stated above we assume that participants start their search for counterexamples by checking situations, which are semantically related to the content of the premises. In addition, reasoners can check situations that are semantically more remotely related to the premise content. Thus, the results suggest that participants with a high working memory capacity can more easily shift from the straightforward type of counterexamples to the more remote type. Participants with a low working memory capacity are rather conservative in their search for counterexamples. It can be argued that the flexibility to change from one semantic domain to another yields a substantial profit in finding counterexamples. Based on our results we can add that working memory capacity is a crucial mediator of this flexibility.

The significant effects on disablers are paralleled by non-significant trends for alternatives. The absence of any significant working memory effects on alternatives can be explained with reference to the structural difference between the two types of counterexamples. When you are asked to generate a disabler, you have to find a situation in which the effect does not occur in presence of the given cause. The presence of the given cause constitutes an important element of the situation you have to generate. As a result you have to

maintain two different propositions, the cause as well as the effect, in memory. For alternatives it is not necessary to maintain the given cause in memory. You just need to look for some alternate causes, and maintain the effect in memory. Markovits argues that for young children, it is harder to search for disablers than to search for alternatives (Jeanveau-Brennan, & Markovits, 1999; Markovits, 2000). We assume that his finding can be generalized to adults. No effect of working memory capacity is observed on alternatives because the generation of alternatives does not challenge working memory capacity in the way that the generation of disablers does.

General Discussion

This article addressed four main issues. First of all, we applied Elio's (1998) taxonomic system for disablers in belief-revision to data gathered in a conditional reasoning perspective. The described system was equally valid for categorizing disablers, as almost all the answers could readily be categorized. Elio (1998) pointed out that belief revision and deductive reasoning are complementary fields of research. This experiment proves that the use of her taxonomic system can be generalized to the domain of conditional reasoning.

Second, we constructed a taxonomic system for generated alternatives. By applying this categorization system we can distinguish different types and categories of alternatives. Although some categories are interrelated, only few answers were subject to discussion. Hence, we conclude that the taxonomy serves its purpose well. In line of Elio's (1998) proposal we suggest that this taxonomic system can also be used for categorizing the alternatives generated in the context of belief-revision. By applying this system researchers are able to shed light on the type of knowledge that is used during the process of belief revision, or in terms of Elio (1998), on the belief-revision operators that people use for resolving everyday contradictions.

Recent research emphasizes the importance of pragmatic and semantic aspects in theories on conditional reasoning (see e.g., Chan & Chua, 1994; Newstead, Ellis, Evans, & Dennis, 1997; Quinn & Markovits, 1998). By outlining two taxonomic systems we provide researchers with an additional methodological weapon for disclosing how the search for counterexamples takes place. These taxonomic systems can also be used for categorizing counterexamples for other types of conditionals than causal ones.

Third, we used the categorization of alternatives and disablers to examine the sort of background knowledge that is advocated during the search for alternatives or disablers. Three broad types of counterexamples were distinguished. The first type contains the 'real' disablers or alternatives. These are descriptions of situations that are semantically close to the stated premises. The second type of answers is of a more 'remote' type. They include answers in which the normal conversational implicatures are suspended. Participants go beyond the usual scheme's (Chan & Chua, 1994) that the premises refer to, in order to find some condition that could not apply (enabler, truthfulness of the speaker, ...). A third category contains answers that are

given just to lengthen the list of alternatives. They include answers referring to some magical interference, plain luck, a non-literal reading or just invalid responses. For a possible rule to decide to start looking in another pool, we can refer to the stopping rule proposed by Johnson-Laird (1994); when it gets too hard to generate another imagined situation, participants stop their search (for alternative stopping rules, see Elio, 2002).

Fourth, we looked at the effect of working memory capacity on the taxonomic distribution of the generated disablers and alternatives. We found that reasoners with high working memory retrieve more disablers and are more flexible in their search. They tend to retrieve different types of disablers while reasoners with low working memory capacity are more conservative. Reasoners with low working memory capacity generated more 'real' disablers than reasoners with high working memory capacity. This result suggests that reasoners with low working memory capacity start by searching the pool of semantically related disablers and are conservative in their search. In contrast, reasoners with high working memory capacity are more flexible in redirecting their search.

We like to add that asking participants to generate as many disablers or alternatives as possible could reflect a somewhat different cognitive process than the process active during the validation phase of reasoning (see also Markovits, Fleury, Quinn & Venet, 1998).

In sum, participants with a high working memory capacity can retrieve more counterexamples and are flexible in their search process. Participants with low working memory generate less counterexamples and restrict themselves to counterexamples of the first type. We find that considering qualitative aspects of generated counterexamples provide valuable information on the underlying cognitive search process. In this study we describe three different types of counterexamples. Furthermore, we argue that working memory capacity is not only a crucial mediator for maintaining and searching information but determines also a reasoner's flexibility to search different semantic domains.

Abstract

This paper aims to study the representational nature of human object-location memory. Two experiments are reported, including both performance data and eye movement data. The results show that multiple allocentric frames of reference are used to encode spatial relationships among objects and late computation in object-location memory retrieval in object-cued conditions is often inevitable. The implications on developing a general model of human spatial cognition are discussed.

Introduction

One important aspect of human spatial memory has to do with remembering the location of objects relative to each other. For example, you might recall that the book you read last night is on your office desk between your computer and the desk lamp. This type of memory for spatial relationships is an essential component of a more general type of memory for spatial layout and is obviously critical for many spatial tasks including locating and navigation (see Tversky, 2000, for a review).

It is not clear, however, how spatial relationships among objects are encoded in memory. While it seems apparent that allocentric frames of reference (i.e., locations defined relative to external objects) rather than egocentric frames of reference (i.e., locations relative to the observer self) are often used to describe these spatial relationships, the representational and computational nature of this description is controversial (see Hunt & Waller, 1999; Klatzky, 1998). For example, are object-based spatial relationships encoded and stored directly (early computation)? Or do they have to be inferred much later at the retrieval stage (late computation)? What factors determine which representational scheme is used?

In this paper we report two experiments we conducted to directly address these issues. The results show that multiple allocentric frames of reference are used to encode spatial relationships among objects and late computation in object-location memory retrieval in object-cued conditions is often inevitable.

This paper consists of three major parts. In the first section, the experimental paradigm is briefly introduced. In the second section, the experiments are reported, including both performance data and eye movement data. In the final section, we briefly discuss our ongoing work of developing

a computational model of the object-location memory and its implications on modeling human spatial cognition in general.

The Experimental Paradigm

We adopted an experimental paradigm developed by Milner and colleagues in the 1990s, which we call the Milner paradigm (e.g., Johnsrude, Owen, Crane, Milner, & Evans, 1999; Milner, Johnsrude, & Crane, 1997; Owen, Milner, Petrides, & Evans, 1996). Though their focus was on neuroimaging studies of the brain foundations of object-location memory, the Milner paradigm offers an elegant experimental design that allows a systematic evaluation of multiple schema for representing spatial relationships. In addition, the availability of neuroimaging data provides invaluable constraints on both understanding behavioral results and developing computational models (e.g., Wang, Johnson, & Zhang, 2001).

There are two phases in the Milner paradigm. In the encoding phase (Figure 1A), eight drawings (objects) are individually presented on a computer screen to subjects, with each drawing accompanied by two landmarks (solid squares). Subjects are asked to remember the locations of drawings, relative to the landmarks. In the retrieval phase, subjects are presented some cues plus two identical drawings. One of the two identical drawings (target) is presented in its original location, and the other one (noise) is presented in a different location (or more accurately, it occupies the original location of another object). Subjects are required to perform a forced-choice recognition of the target, relative to the cues. Milner and colleagues originally used four retrieval conditions:

1. In the fixed-landmark condition (Figure 1C), the two landmarks were presented as cues, along with the target-noise pair. The absolute location of landmarks and objects on the screen was unchanged from their original encoding positions.
2. In the shifted-landmark condition (Figure 1D), the two landmarks were presented as cues, along with the target-noise pair. Though the spatial relationships among the landmarks/drawings remained unchanged, the absolute locations of the landmarks/drawings on the screen were shifted.
3. In the fixed-object condition (Figure 1E), two encoded drawings instead the two landmarks were

presented as cues, along with the target-noise pair. The absolute locations of drawings on the screen were unchanged.

4. In the shifted-object condition (Figure 1F), two encoded drawings instead the two landmarks were presented as cues, along with the target-noise pair. Though the spatial relationships among the drawings remained unchanged, the absolute locations of the drawings on the screen were shifted.

One significant feature of the Milner paradigm is that it simultaneously involves multiple spatial representations, including screen-based, landmark-based, and object-based. While landmark-based representations are perceptually accessible in the encoding phase (because an object was always presented along with the two landmarks in the encoding phase), object-based representations are not (because no two objects are presented at the same time in the encoding phase). Therefore, this fact alone might suggest that object-based retrieval would be harder than landmark-based retrieval. Systematic alignment of the different testing conditions allowed Milner and colleagues to use a subtraction method to determine the brain areas that dominate in the different test conditions.

Behavioral data was only briefly reported in Johnsrude et al (1999). It was found that the shifted-object condition was harder (e.g., longer RTs and lower accuracy) than any other conditions, which did not differ from each other. Neuroimaging data suggested that object-location memory in general involved the parahippocampal system, and the shifted conditions, as compared to the respective fixed-conditions, activated the posterior inferotemporal cortex. Both areas have been believed to subserve important functions of spatial cognition (e.g., Burgess, Jeffery, & O'Keefe, 1999).

Experiment 1

In Experiment 1 we added one more testing condition to the original Milner paradigm. In this additional condition, called the fixed-nocue condition, no cues were presented along with the target-noise pair in the retrieval phase. Subjects had to make the forced-choice based solely on the absolute location of objects on the screen. This condition was added to explicitly test the effect of screen-based spatial representations in location retrieval.

Another purpose of experiment 1 was to collect eye movement data. Both perceptually encoding and cognitively computing spatial relationships invite eye movements. The trace of natural eye movements during the task provides an indication of the deployment of attention (e.g., Corbetta et al., 1998) and may shed light on the underlying spatial representations and operations (e.g., Colby & Goldberg, 1999).

Subjects, Apparatus, and Materials

21 subjects, 8 females and 13 males, with normal or corrected-to-normal vision, were paid to participate in the experiment. Five sets of stimuli (each consisting of eight drawings) were created using digitized black and white

representational drawings of common objects, selected from the database of (Snodgrass & Vanderwart, 1980). The drawings, 100x100 pixels in size, were presented against a white background on a 19" VGA monitor with a resolution of 1024x768. The monitor was in front of the subjects within 2 feet. Subjects were asked to respond by clicking with a mouse which was within comfortable reach. 11 subjects wore a head-mounted ISCAN eye-tracker while they were doing the experiment.

Design and Procedure

Each subject performed all 5 experimental conditions, each with a different stimulus set. The design is illustrated in Figure 1.

In each encoding trial, subjects were presented one drawing and two landmarks and were instructed to remember the location of the drawing relative to the landmarks. Subjects clicked the drawing to go on to the next trial. There were 32 encoding trials in each condition, with each drawing presented 4 times. The presentation order was randomized. During the study subjects did not know which testing condition would follow.

In each retrieval trial, subjects were presented the cues and the target-noise pair according to the testing condition. Subjects were instructed to choose the target, by clicking, as quickly as possible and as accurately as possible. As soon as the subjects clicked, the next trial was presented. Each drawing was tested 4 times.

Figure 1. The design of Experiment 1. A, an encoding trial; B, fixed-nocue retrieval; C, fixed-landmark retrieval; D, shifted-landmark retrieval; E, fixed-object retrieval; F, shifted-object retrieval.

Results

Accuracy data. The average accuracy was at least 93%, and there was no difference among the 5 testing conditions.

Figure 2. RT data in Experiment 1. The error bars represent 95% confidence intervals.

RT data. The reaction time data is shown in Figure 2. An ANOVA shows a significant interaction between the cue type (landmark vs object) and the array type (fixed vs shifted). In addition, a post-hoc comparison shows that the shifted-object condition takes significantly longer than any other conditions, consistent with Johnsrude et al (1999) results.

Eye movement data. Eye movements are needed to search the scene and measure spatial relationships. The number of eye fixations in each trial is counted and reported here. The result is shown in Figure 3. It is interesting to note that the eye fixation pattern is remarkably similar to the RT pattern, indicating that the number of eye fixations is a good predictor of RT.

Figure 3. The number of eye fixations in Experiment 1.

Summary & Discussion

Experiment 1 resulted in two major findings that have not been reported by Milner and colleagues. First, the reaction time in the fixed-nocue condition was not different from that in the fixed-landmark condition. Since a screen-based spatial representation had to be used in order to perform the fixed-nocue condition, this result indicates that a screen-based spatial representation might be *implicitly* encoded and stored (because subjects were specifically instructed to pay attention to the drawing's location relative to the landmarks), and be adopted to perform the fixed-landmark condition. This hypothesis was further supported by the eye movement data. The number of eye fixations in both conditions was about 2, the minimal fixations needed to identify the target if a conservative check-both-target-and-noise-before-click strategy was used. The eye movement traces also indicated that subjects often ignored landmarks in the fixed-landmark condition.

Second, the significant interaction between the cue type (landmark vs object) and the array type (fixed vs shifted) was surprising. The reaction time in the shifted-object condition was significantly longer than that in any other conditions (the RT in the shifted-object condition was about 1800ms, 2100ms, and 2700ms longer than that in the fixed-object, shifted-landmark, and fixed-landmark conditions, respectively, see also Table 1), indicating some additional operations occurred in that condition. An analysis of the computational differences among conditions sheds light on what these operations could be. a) Landmark cues (solid squares) were much more perceptually distinct than object cues. In both object-cued conditions, an additional search operation was necessary in order to distinguish the target-noise pair from the two object cues. b) Compared to the fixed conditions, both shifted conditions required explicit access of spatial relationships, either landmark-based or object-based. While landmark-based spatial relationships might be directly encoded in the encoding phase and later directly retrieved in the retrieval phase, it seems that object-based spatial relationships had to be derived through late computation because subjects never saw any two objects at the same time.

Eye movement data, however, indicated that this hypothesis might be oversimplified. In the encoding phase, we quite often observed that subjects moved his/her eyes back and forth between the currently presented object and the location of the previously displayed object (in the previous trial, which has already disappeared), indicating some form of object-based spatial relationships might be encoded directly and quite early. In general, however, it seems likely that shifted-object conditions involved quite extensive late computation in determining object-based spatial relationships.

We speculate that a race model can be used to explain the data. Specifically, when multiple types of representations for spatial relationships are available to solve the task at hand, they compete. Though often the representation that affords easiest operations dominates, sometimes they

interfere with each other. A decomposition of the representations/operations for each condition is summarized in Table 1. It seems that the race model explains the RT data reasonably well.

Table 1: A representational decomposition

	RT (ms)	Accessible representations/operations		
		Early computation	Late computation	Addn. ops
Fixed- nocue	1874	Screen-based		
Fixed- landmark	1723	Screen-based		
Fixed- object	2599	Screen-based	Object-based	Search
Shifted- landmark	2324	Landmark-based		
Shifted- object	4402		Object-based	Search

Experiment 1 raised two issues. The first one is the role of search in the object-cued conditions. Since the target-noise pair and the object cues are visually indistinguishable, a non-spatial visual search component is necessary to perform the task. The search component was a free parameter in the above race model that could be estimated but it obviously confounded the results. It would be useful to eliminate this confound. The second issue also has to do with the object-cued conditions. In Experiment 1, the two objects that were chosen to be cues in each trial were randomly selected from all possible objects (i.e., those that were not the target-noise pair). This made the task hard in the sense that all possible object-based spatial relationships (there were 7^8 of them!) might be relevant in the retrieval phase. This was in sharp contrast with the landmark-cued conditions, which had only 16 relevant spatial relationships (8 for each landmark). Therefore, it might be the pure number of relevant spatial relationships but not the late computation of object-based representations that made the object-cued conditions more difficult. We designed experiment 2 to explore these two issues.

Experiment 2

Experiment 2 adopted the same Milner paradigm, but differed from Experiment 1 in three aspects. First, the landmarks were changed from solid black squares to a white-filled black square. Second, in the object-cued conditions, the object cues were framed in a black squared to make them visually salient. The purpose of the change was to eliminate the search component in retrieval. Third, we added two more object-cued conditions, which we called consistent mapping conditions. In these conditions, instead of selecting two cue objects at random for every trial, the two objects were selected at the beginning of the testing session and consistently served as the object cues for every trial in that session. This change greatly reduced the relevant spatial relationships and could be viewed as a middle

condition between the pure object-cued condition and the pure landmark-based condition.

These changes resulted in six testing conditions, as shown in Figure 4. 14 subjects were paid to participate in the experiment.

Figure 4. The design of Experiment 2. A, fixed-landmark retrieval; B, shifted-landmark retrieval; C, fixed-object retrieval; D, shifted-object retrieval; E, fixed-object consistent mapping retrieval; F, shifted-object consistent mapping retrieval.

Results & Discussion

Accuracy data. The average accuracy was at least 88%, and there was no difference among the 6 testing conditions.

RT data. The reaction time data is shown in Figure 5. An ANOVA reveals similar effects to Experiment 1, including the significant interaction between cue types (object vs landmark) and array types (fixed vs shifted).

The effects of the two manipulations we adopted in Experiment 2 were evident. First, combining the results from both experiments, it is clear that the elimination of the search operations (by framing the object cues) did decrease reaction time in certain object-cued conditions. However, this time saving had a surprising interaction with the array types. Specifically, while the time saving in the fixed-object condition was not significant (2599ms in Experiment 1 vs 2494ms in Experiment 2) the saving was significant in the shifted-object condition (4402ms in Experiment 1 vs 3548ms in Experiment 2). It is not so obvious how to explain this interaction. Second, the manipulation of consistent mapping in object-cued conditions also reduced

the reaction time. However, again, a reliable interaction with array types was found. While the time reduction was about 450ms in the fixed-object conditions (2494ms vs 2044ms), the reduction was about 900ms in the shifted-object conditions (3548ms vs 2640ms). Similarly, it is not obvious how this interaction occurred without a detailed computational model.

Figure 5. RT data (in ms) in Experiment 2. The error bars represent 95% confidence intervals.

Eye movement data. Similar to Experiment 1, eye movement data corresponded quite well with the reaction time data (see Figure 6). Fewer numbers of eye fixations were observed in the fixed array conditions than in the shifted array conditions. In addition, the object-cued conditions induced more eye fixations than the landmark-cued conditions. In particular, both the elimination of the search component and consistent mapping in object-cued conditions significantly reduced the number of eye fixations (by about 1 and 1.5, respectively), indicating both manipulations successfully reduced the efforts of object recognition and late computation of spatial relationships.

Figure 6. The number of eye fixations in Experiment 2.

General Discussion

Memory for object-location is an essential aspect of human spatial memory. However, the underlying representational mechanisms and computational operations are controversial. The empirical study reported here adopted and extended the Milner paradigm and produced interesting data toward a better understanding of the problem. In this section, we would like to discuss three issues related to the implications of the study and the future work.

First, the current study supports the argument that memory for spatial relationships can take multiple forms of representations, each encoded in a different frame of reference. Some of these representations may result from an early computation, often due to a direct perceptual experience in the early encoding phase. These representations can be encoded implicitly, such as the screen-based representations, or explicitly, such as the landmark-based representations and some object-based representations (e.g., spatial relationships between objects presented in consecutive trials). However, most of the object-based spatial relationships have to be inferred when necessary through a late computation, resulting in longer reaction time in the object-cued conditions. When multiple forms of representations are simultaneously available, a race model seems plausible. The processes supported by each representation compete with each other, and typically the one that affords fast response dominates. Eye movement results support this hypothesis.

Second, the results from the current study are also consistent with the neuropsychological evidence that suggests there exist multiple spatial representational systems in the brain (e.g., Burgess et al., 1999; Wang et al., 2001). The PET imaging results from Milner and colleagues (1997) revealed that when object-location memory is retrieved, brain activity increases in the parahippocampal system, an area that is generally believed to subserve allocentric spatial representations.

Finally, while the current study generated interesting results, it is clear that to fully understand these results a detailed computational model is necessary. Questions about how multiple forms of spatial relationships are represented and how they interact can be better explored only when a computational model is developed. Efforts are being taken to develop such a model in the Act-R cognitive architecture (Anderson & Lebiere, 1998). The long-term goal is to develop a framework that can be used to model human spatial cognition in general, including object-location memory and spatial layout memory.

Abstract

The SHRUTI model demonstrates how a system of simple, neuron-like elements can encode a large body of *relational* causal knowledge and provide the basis for rapid inference. Here we show how a representation of utility can be integrated with the existing representation of belief, such that the resulting architecture can be used to reason about values and goals and thereby contribute to decision-making and planning.

Introduction

To understand how the brain creates the mind, one could work mainly from the top down, characterizing mental processes, or from the bottom up, trying to understand the capabilities of neurons and simple circuits. In developing the SHRUTI model we have pursued both these approaches simultaneously in order to understand how networks of neurons can perform complex cognitive tasks. In past work, we have demonstrated how such networks can make predictive and explanatory inferences with respect to a large body of causal knowledge. In this paper, we show how the SHRUTI architecture can be extended to represent and reason not only about beliefs but also about utilities, values and goals. The resulting model uses a single causal structure to seek explanations, make predictions, and identify expected utilities of world states and actions.

The SHRUTI architecture

First we present the basic elements of the SHRUTI architecture. The model is described in considerably more detail in [Shastri, 1999, Shastri and Ajjanagadde, 1993, Shastri and Wendelken, 2000]. SHRUTI is a neurally plausible (connectionist) model that demonstrates how a network of neuron-like elements could encode a large body of structured knowledge and perform a variety of inferences within a few hundred milliseconds. SHRUTI suggests that the encoding of relational information (frames, predicates, etc.) is mediated by neural circuits composed of *focal clusters* and that the dynamic representation and communication of relational instances involves the transient propagation of *rhythmic* activity across these clusters. A role-entity binding is represented in this rhythmic activity by the *synchronous* firing of appropriate cells.

Figure 1: Diagram showing core elements of the SHRUTI model, including relational focal clusters, a fact, a rule, and a simple type hierarchy.

A focal cluster is a collection of nodes with varying functionality all subserving a common representation. A relational focal cluster consists of a positive (+) and a negative (-) collector node, an enabler (?) node, and role nodes. The activity of the positive (negative) collector node reflects the amount of evidence collected in support of belief (disbelief) in the given relation. Activity of the enabler (?) node reflects the strength with which information about the relation is being sought. A link from collector to enabler ensures that the system automatically seeks explanation for what it believes. Role bindings are represented by synchronous firing of relational role nodes with nodes in a connectionist type hierarchy. A relational cluster with active role bindings represents a relational instance. Rules are encoded with links that enable the propagation of rhythmic activity from one relational focal cluster to the next. Specifically, a rule is formed by linking the antecedent collector to the consequent collector, the consequent enabler to the antecedent enabler, and matching role nodes in both directions, through an intervening focal cluster

termed the *rule mediator*. Type restriction and instantiation of unbound variables are handled via connections between the rule mediator structure and the type hierarchy. Long-term facts are encoded in SHRUTI as temporal pattern matching circuits. *Episodic facts* (E-facts) are tuned to particular relational instances and represent specific knowledge or memories, while *taxon facts* (T-facts) are typically responsive to a range of relational activations and represent more general statistical knowledge about the world.

Probabilistic reasoning

Previous work has shown that the inferential behavior of SHRUTI does not, in most cases, stray far from a probabilistic ideal [Wendelken and Shastri, 2000]. With appropriate assignment of link weights, a simple rule structure can be shown to compute probabilities correctly in both the forward and backward direction. A set of evidence combination functions allows for flexible combination of evidence from multiple sources, while maintaining a relatively simple connectionist structure in which each antecedent communicates with the consequent via a single weighted link [Shastri and Wendelken, 1999]. Explaining away occurs via inhibitory interconnections between antecedents, so false patterns of circular reasoning are not introduced.

Inference in SHRUTI is essentially an anytime algorithm. Unlike in a belief net, responses to a query are generated almost immediately, based on the prior information stored for the queried relation. As inference is allowed to progress, early estimates are repeatedly refined as more and more evidence is brought in from further up or down the causal chain. In a neural system, the depth to which this search for evidence occurs would be limited, such that only evidence within a certain distance (along any casual chain) would be considered. Presumably, this depth could be modulated by attention or other factors. Importantly, this is a model which scales up naturally to large domains without performance loss (with reference to a parallel network of nodes and links).

Figure 2: An illustration of the link weights for a simple rule (roles not shown). If B is believed true (+:B active with value 1.0) then activity at +:A will equal $P(A|B)$

Representing utility in SHRUTI

SHRUTI's representation of utility [von Neumann and Morgenstern, 1947] is analogous to its representation of belief. This consists primarily of a set of utility nodes associated with each relational focal cluster, reward facts denoting reward and punishment, value facts denoting learned utility values, probabilistically weighted utility-carrying connections between relations, and various modulatory mechanisms that affect utility flow differently in different situations. Thus belief and utility in SHRUTI are tightly integrated, sharing much of the same structure, and are not separate modules in any conventional sense.

Utility nodes

Recall that the representation of beliefs in SHRUTI is built around relational focal clusters, which contain several different types of nodes including positive and negative collectors, an enabler, and role nodes. Alongside these nodes representing belief, there are additional nodes representing associated utility. Thus there is a utility node tied to each of the two collectors, with activation range $[-1,1]$. These nodes are denoted by \$+ and \$-; positive activity of \$+ (\$-) indicates that positive utility value is associated with the truth (falsity) of the relation, while negative activation value of \$+ (\$-) indicates that negative utility is associated with the truth (falsity) of the relation. Links from each utility node to the enabler node ensure that whenever something is marked as having utility, it is automatically investigated by the system.

Activation of a relational utility node can indicate that reward is currently being experienced, or that it is expected. In either case, it reflects not only reward that is directly associated with its relation (as, for example, satisfying a sweet tooth is associated with eating cake), but also sources of reward that are more distantly related (such as potential weight gain). In this respect, the utility node is comparable to the value function of traditional reinforcement learning; however, utility node activity is transient and cannot by itself represent any permanent learned value associated with a relation instance (how this information is maintained will be described shortly). Instead, activity at a relational utility node reflects the combination of more permanent representations of value with the transient factors that make up current context.

Reward facts

Some relations have *reward facts* (R-facts) tied to them, designating certain relational instances as goals. Reward facts represent the source of reward and punishment in the system. Activation of a positive reward fact indicates the attainment (real or imagined) of some reward, while activation of a negative reward fact indicates the suffering (real or imagined) of some punishment. Like episodic facts in the belief system, reward facts are temporal pattern matching circuits that respond only when the specified set of role-fillers are active. In this case, activation of a relational collector along with synchronous activation of role nodes and appropriate type

node role fillers leads to activation of an associated fact node, which in turn leads to activation of that relation's appropriate utility node. Many different reward facts can be linked to a single relation; for example, a relation like *eat(x)* might have associated with it positive reward facts such as *eat(Cake)* as well as negative reward (punishment) facts such as *eat(Dirt)*.

Figure 3: Two reward facts for the relation *eat(x)*

Research with rats and brain-stimulus reward suggests that both idiosyncratic and common currency representations of utility exist in the brain [Shizgal, 1998]. The representation of utility as activation values of relational utility nodes is a common currency representation which allows the activity of one node to be directly compared to the activity of another in order to guide decision-making. This is vital in order to allow successful decision making that takes into account disparate sources of reward and punishment. More domain-specific representations of utility must also exist, since the relative weighting of utilities from different sources can vary. The utility of eating, for example, is greatly influenced by degree of hunger, while the utility of play is not. Reward facts represent the connection between the common currency and the more domain-specific representations of utility. In order to model the latter, we allow that the weights on reward facts might vary depending on some internal state of the agent.

Value facts

While relational utility nodes represent value estimates in the current context, and reward facts represent basic goals, the task of storing learned value estimates rests with the *value facts*, or V-facts. Value facts are similar in form to reward facts, but instead of directly representing reward, they represent predicted future reward. For both value facts and reward facts, utility values are stored as link weights (specifically, as the weight on the link leading from the fact node to the associated relational utility node). The value fact associated with a relation plays a similar role to the value function in traditional reinforcement learning, and the update function for a value fact, depending as it does on local reward and maximization (or some other combination) of utility values of possible consequents, closely resembles the Bellman equation [Bellman, 1957]. Note, however, that value updates in SHRUTI depend only on activity of a

few connected predicates, and not on the entire system state. Because of the similarity in the Bellman equation and SHRUTI's value-updating algorithm, the latter has been termed Causal Heuristic Dynamic Programming (CHDP) [Thompson and Cohen, 1999]. Like taxon facts in the belief system, value facts hold a statistical summary of past activity. They too are associative, meaning that matching of relational activity to the fact is stronger with more role matches, but is not necessarily blocked by a single role mismatch; this helps with generalization of value to multiple related instances.

A typical relation has many value facts associated with it, some very specific and some quite general. In this way, particularly important or salient items are explicitly encoded, whereas novel or less important items can fall back on more general representations. For the hypothetical agent for which eating cake is a paramount goal, *find(Cake)* should be a highly-rewarding value fact. Eating other things may still be beneficial, so the more general *find(Food)* may also appear as a weaker value fact; finding anything is more often good than bad, so even the most general value fact *find(Thing)* might appear in the agent's internal representation. When the agent with these value facts happens upon a dollar bill, it will immediately perceive this as a positive situation according to the value of the *find(Thing)* value fact. If finding money turns out to be significantly more rewarding than finding that average-value random thing, then this should be learned and explicitly represented as a new value fact.

Communication of utilities

Links connect utility nodes of different relations in the same way that they connect belief nodes. These links run parallel to the belief system connections, but in the consequent to antecedent (backward) direction. Figure 4 provides a simple illustration of these connections: for the rule $A \wedge B \Rightarrow C$, there are utility connections from the utility nodes of *C*, through the rule mediator, back to those of *A* and *B*. Weights on these connections are similar to the weights on the collector-collector links. Their purpose is to introduce probability into the calculations of value, such that the value estimate at some antecedent relation is based on both the value of its consequent (activity at its utility node) and the probability that it will be reached (weight on the connecting link). For the rule $A \Rightarrow C$, where the utility node of *C* ($\$C$) has a value of α , the utility node of *A* ($\$A$) should obtain the value $\alpha \times P(C|A)$.

This structure has the effect that assertion of a particular goal, via activation of a utility node, leads in the simplest case to assertion of its potential causes as subgoals, via spreading activation backwards along the causal chain. Belief in some relation, represented as activation of a collector node, leads to internal reward or punishment (activation of a reward fact) or recognition that such reward or punishment is likely (activation of a value fact) if there is an intact causal chain leading from that relation to some goal relation.

Figure 4: A diagram showing structure of utility connections for a two-antecedent rule.

Utility modulation

The model of utility propagation described so far is perfectly adequate for simple cause-effect relationships or chains of these. However, with multiple-antecedent or multiple-consequent rules, or with multiple rules involving a common relation, additional mechanisms must be introduced. Consider first a rule with two antecedents, such as $find(x) \wedge edible(x) \Rightarrow eat(x)$. The utility of finding something, which is derived from the utility of eating something, depends directly on whether or not that thing is edible. Thus, there should be an interaction between the two antecedents such that if $edible(x)$ is false, then the propagation of utility from $eat(x)$ to $find(x)$ is at least partially blocked. The reverse holds true as well - utility of a thing being edible depends not only on the utility of eating it, but also on whether or not it has been found.

The interaction described here is appropriate for the *and*-combination, but different interactions should occur when different relations hold between the antecedents and the consequent. For example, when antecedents are combined with an *or* function, then belief in the truth of one should tend to discount the propagation of utility to the others. In this case, when one cause is established, then redundant causes are no longer particularly useful. For the *avg* (weighted average) function, each antecedent contributes independently to the total, and so belief in the truth of one antecedent should have no impact on the perceived utility of another.

In general, the utility value at an antecedent relation should reflect the value of any associated consequents times the extent to which truth of the antecedent affects truth of the consequent. For a rule with antecedents A and B_1 through B_n and consequent C , this might be stated as "What difference does A make, in the context $B_1 \dots B_n$, for the attainment of C ", or in terms of probabilities, $P(C|A, B_1 = b_1, \dots, B_n = b_n) - P(C|\neg A, B_1 = b_1, \dots, B_n = b_n)$.

If the above expression is expanded for each different combination function, an interesting result is obtained, namely, that it is possible to compute it exactly for each different combination function using only the existing weight on the utility link along with a single additional weight from each associated antecedent. This relative

simplicity of the resulting connectionist structure is important, since it lends plausibility to the notion that such a mechanism could be learned in the brain. Results for three combination functions, *and*, *or*, and *avg*, are shown below. The connectionist structure that computes these functions is shown in figure 4.

ECF	$\$: A / \$: C$
<i>and</i>	$W_A \cdot \prod_{i=1}^n (1 - (1 - b_i)W_{B_i})$
<i>or</i>	$W_A \cdot \prod_{i=1}^n (1 - b_i W_{B_i})$
<i>avg</i>	W_A

Action focal clusters are given special treatment within this framework. Since the agent has control over whether or not an action is performed, activity of an action collector does not modulate the utility values flowing to any sibling antecedents. Also, while activity of an action's utility node indicates that the action is beneficial or harmful, activity of its enabler simply indicates that the action is potentially relevant.

Distribution and recombination

Just like beliefs, utilities from different sources must be combined. In general, the same approach is used here as with calculation of belief - a range of simple evidence combination functions are available and can be inserted into the connectionist structure as appropriate. Because many rewards are generally better than one, combination functions selected should generally have the property that a combined utility value is greater than any of the individual utilities; summation and *or* are two likely candidates. However, using such a combination function leads to a difficult problem when we allow multiple paths to exist between two relations. Consider the scenario, illustrated in figure 5 where exploration can lead to finding fruit or finding game, and that either of these consequents can lead to the goal relation of being able to eat. Utility associated with eating is propagated in full to both *findFruit* and *findGame* (assuming an *or*-combination and that neither is currently true), and from each it is further propagated back to *explore*. Now if *explore* has the sort of combination function described above, it can obtain a local utility value greater than that originating at the goal *eat*. This is clearly an unacceptable situation, and it comes from the fact that locally there is no information to distinguish between utility arriving from different sources (which should be added together) and utility values that originate from the same source (which should not).

One solution to this problem might be to disallow multiple paths between relations. Indeed, this is the solution adopted for belief nets to solve essentially the same problem. However, connections between relations are assumed to be learned from experience based only on local information; it is difficult to imagine any plausible mechanism by which learning of multiple paths could be inhibited when these provide the best fit for experience. Another solution would be to reduce the amount of utility distributed along each path according to the number

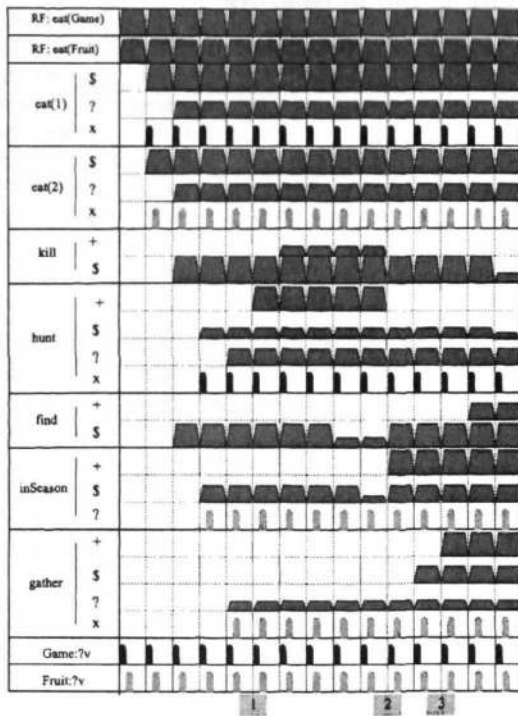

Figure 7: A stylized trace of node activations during execution of the caveman scenario.

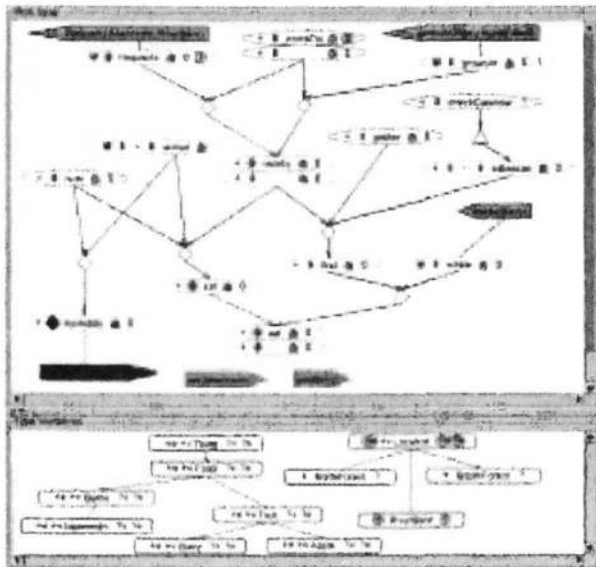

Figure 8: An expanded version of the caveman scenario.

In order to deal effectively with complex decision tasks, a measure of higher-level control must be introduced. Extensions to the model described here that enable it to perform complex decision-making and planning are described elsewhere [Wendelken and Shastri, 2002, Garagnani et al., 2002].

Abstract

In this paper we present a methodology for improving the reliability of observers in magnitude estimation tasks by using the computer to augment the cognitive components of the task.

Psychophysical scaling is the study of how to accurately measure perception. More specifically, the goal is to find methodologies that allow people to accurately communicate the magnitudes of specific dimensions of conscious experience, such as brightness, loudness, temperature, and heaviness. Psychophysical scaling can also be used for measuring the magnitude of subjective experiences such as level of happiness (e.g., West & Ward, 1988). The goal of psychophysical scaling is to find the mathematical functions that map the magnitudes of external stimulus dimensions to the conscious perception of magnitude. This enterprise is extremely useful for both scientific and applied research.

Numerous different scaling techniques exist. However, our focus is on magnitude estimation, which is one of the most commonly used psychophysical methods. Magnitude estimation (ME) was invented by Stevens (1956) and involves exposing subjects to a set of stimuli and asking them to match the magnitude of a particular dimension of each stimulus to the magnitude of a number. This is repeated for multiple trials to provide multiple responses for each stimulus value. To avoid the influence of outliers, the median or the geometric mean of the responses for each stimulus value is calculated. Numerous studies have shown that plotting these values against the stimulus values produces functions that are closely approximated by power functions. This is known as, the Power Law, or, Stevens' Law.

The form of the power law is,

$$R=KS^B,$$

where R is the observer's response, S is the stimulus magnitude, B is the exponent value, and K is a constant. Logging both sides of the equation produces,

$$\text{Log}(R)=B \cdot \text{Log}(S)+\text{Log}(K),$$

which is a straight line with B estimated by the slope and K by the intercept. The exponent, B, can be interpreted as a metric for stimulus compression. This reflects the fact that people use a power function or something closely

approximating a power function to compress stimuli, just as audio and video files can be compressed to save on bandwidth. In fact, audio and video compression go unnoticed to the extent that the compression function maps onto the human compression function for the same stimuli. Generally speaking, in ME the goal is to put as few restrictions on the observer's choice of numbers as possible. Often free ME (e.g., see Zwislowski & Goodman, 1980) is used, in which observers are instructed to match the perceived magnitude of the stimulus to whatever number seems most natural. This is quite different from the common psychological practice of imposing scales on people. The reasons for this are both theoretical and practical. From a mathematical standpoint, if any two stimuli are set equal to any two responses then you have determined what the exponent value must be. Thus, if an observer uses the lowest value on a scale to match the lowest perceived magnitude and the highest value to match the highest perceived magnitude, the power function exponent has been fixed. To get around this one could assign a value to a middle value on the scale and not impose a top end or bottom end, but this has been shown to produce confusion and poor results (Stevens, 1975). However, the fact that peoples' backgrounds cause them to use different ranges of numbers in their responses is not a problem as these differences are captured by the K constant (since response range is usually not of interest, K values are usually not reported).

ME can be considered a special case of cross modal matching (CMM). In cross modal matching, the observer adjusts the magnitude of one stimulus dimension to match the magnitude of another stimulus dimension (e.g., adjusting the brightness of a light to match the loudness of a tone). Like ME, CMM results also produce power functions. Furthermore, ME and CMM results are consistent in that they can be used to predict each other (e.g., the ME exponents for brightness and loudness can be used to predict the exponent relating brightness and loudness in a CMM experiment). Also, both the power functions and the specific exponent values found through ME are consistent with ratio scaling experiments, in which magnitude scales are derived by asking observers to set or report ratios between stimuli. These approaches to scaling are known as direct scaling techniques (Stevens, 1971).

Problems

ME forms the foundation for a potentially accurate and consistent way of measuring perceived magnitude. However,

ME, as well as the other methods with which it is consistent, have been found to be limited in terms of accuracy. Although a considerable amount of evidence indicates that subjects do obey the power law (see Stevens, 1975; and Bolanowski & Gescheider, 1985 for reviews), the specific exponent values that Stevens found could not be reliably replicated with the level of accuracy one would expect for measuring sensory processes in normal, healthy individuals. Exponent values vary considerably across individuals in the same experiment (e.g., Algorn & Marks, 1984; Luce & Mo, 1965; Marks & J. C. Stevens, 1965; Rule & Markley, 1971; Wanschura & Dawson, 1974; Logue, 1976) and can also vary across time within individuals (Logue, 1976; Marks, 1991; Teghtsoonian & Teghtsoonian, 1983). Stevens also found strong individual differences, which he attributed to various response biases. Stevens' solution was to treat response bias as a random factor and to average across individuals to get the true exponent value (Stevens, 1971). However, Marks (1974) reviewed the literature and found that in addition to individual differences, the average value of the exponent varies significantly across ME experiments done in different labs. These results suggest that the distribution of individual response biases differs from lab to lab, indicating that they cannot be treated as random. Indeed, it is well known that some labs get systematically higher or lower exponent values than others, suggesting that response bias can be influenced by minor procedural differences.

In addition to limitations on accuracy, ME results are not consistent with partition scaling (also called interval scaling) results for prothetic continua, although they are consistent for metathetic continua (according to Stevens, metathetic continua are more qualitative in nature, e.g., pitch or hue; while prothetic continua are more quantitative in nature, e.g., loudness or brightness; see Stevens, 1971 for a more detailed discussion). Partition scaling includes a variety of techniques that require observers to partition the stimulus continuum. Category scaling (e.g., 1 to 5 scales; 1 to 7 scales; scales partitioned by word labels such as good, bad, very bad) is a form of partition scaling, and is by far the most commonly used scaling technique. The problem is that partitioning techniques tend to produce power functions with lower exponents than direct scaling techniques (Stevens, 1971). Stevens' argument for accepting the results of direct scaling techniques rather than partition scaling techniques was that partition scaling is less direct because it requires the extra step of partitioning the stimulus range, and that the discrepancy can be attributed to biases introduced by the partitioning task (see Stevens, 1971). However, like direct scaling, partition scaling also produces excessive variability (Marks, 1974).

Because of these problems, psychophysical scaling still has issues concerning reliability and validity. In terms of the power law, the validity problem can be stated as the problem of which, if any, method will produce the "true" exponent. The reliability problem is that we do not have a methodology that we can use to make reliable statements about individual differences or inter-lab differences in exponent values. In our opinion, the reliability problem needs to be solved before tackling the validity problem. Our

work attempts to address this. The reliability problem can be broken down into a theoretical and a practical problem. The theoretical problem is that if bias differs from individual to individual and within individuals across time, we cannot get reliable measurements without being able to somehow predict or control the bias. The practical problem is that even if we solve the theoretical problem, to be useful we need a system that does not require huge numbers of responses from individuals who have limited amounts of time and limited attention spans. We have focused our efforts on the reliability issue and attempted to solve both of these problems by cognitively augmenting our human observers through the use of computerized support.

Bias

The process of magnitude matching can be represented in the following way (Marks, 1991),

$$M(S) = R$$

where S is the stimulus magnitude, R is the response magnitude, and M is the function relating them. The M function can then be decomposed into an initial, perceptually based function, P , that is the same (or highly similar) across healthy, normal individuals; followed by a function, C , representing cognitively imposed constraints that account for the excessive variability:

$$M(S) = C(P(S))$$

Since most psychophysicists study perception, the emphasis has been on getting rid of C so as to reveal P . Considerable effort has been expended in this enterprise. Approaches taken include trying to identify the sources of C to avoid or control for them (see Poulton, 1989 for a review); trying to minimize C by encouraging observers to respond naturally, without thinking about it too much (e.g., Stevens, 1975; Zwislocki & Goodman, 1980); trying to measure C and then partial it out (e.g., Berglund, 1991); trying to stabilize C across scaling tasks to get rid of intra-observer variability (e.g., J. C. Stevens & Marks, 1980); and avoiding C by developing methods that allow the scale to be derived from judgments of "greater than" or "less than" for paired stimuli sets (e.g., Schneider, 1980, 1988). However, success in these endeavors has been limited and a consensus as to the best method is lacking.

Our approach to dealing with C was quite different. As cognitive scientists, we viewed the variability of C as the inevitable consequence of the sort of problem presented to the observers, i.e., create and maintain a consistent mapping from P to R . The problem of creating a mapping may or may not be difficult but it is definitely open ended, with very few constraints on the solution. Also, the problem of maintaining the mapping once it has been created could tax the limits of working memory. In fact, Petrov and Anderson (2000) and Petrov (2001) were able to model a number of different bias effects associated with various factors using the ACT-R (Anderson & Lebiere, 1988) architecture to model the memory processes involved. Based on this view, our approach has been to attempt to eliminate these effects by

providing computerized support for establishing and maintaining the scale.

Constrained Scaling

Constrained scaling is a form of magnitude estimation (i.e., observers report numbers to match stimulus values). The goal of constrained scaling is to calibrate observers to the same C function before scaling the stimulus dimension of interest, similar to the way that physical measuring instruments are calibrated before use (Ward, 1991). Constrained scaling (West, Ward, & Khosla, 2000) is based on four claims about C : (1) that C is cognitively penetrable, (2) that C is heavily influenced by ad hoc decisions made early in the scaling process, (3) that the C process makes heavy demands on working memory which leads to instability across the task, and (4) that C is independent of the perceptual modality being judged (i.e., if the perceptual modality is changed it does not directly cause a change in C , although an interruption in the process could disrupt and indirectly alter C). Provided these assumptions are true, it should be possible to train observers to use a predetermined C function, and to support the maintenance of it in memory by refreshing it through a computerized feedback system.

Constrained scaling involves two phases, a learning phase and a test phase. In the learning phase, feedback is used to train observers to respond to a standardized set of stimulus magnitudes according to a predetermined response scale. This is done across several trials by presenting learning set stimuli and having the observer rate the perceived magnitude by entering an R value. On the interface we have been using this can be done by entering a value in a text box or by using a specially designed scroll bar that allows the observer to move the slider by units of 10, 1, 0.1, and 0.01. The scroll bar runs from 0 to 100 (although the observers are instructed that they may enter R values above 100). After this the observer clicks a button marked, "OK," and their R value is replaced with the correct R value. The point of this is to build C functions that are the same across observers and to give them the practice they need to become familiar with it. Provided that P is highly similar across observers, training the observers so that they all correspond to the same function relating S and R , implies they have the same C function, although it is possible that the details of how they cognitively implement and maintain the C function may differ.

The choice of the scale to be learned should be based on learnability and the mathematical desirability of the scale. Similar to West et al (2000), we used a power function with an exponent similar to what would be found using ME (i.e., we accept, to some extent, Stevens' argument that free ME produces scales that people find more natural to use) and K was set so that the scale range was approximately from 1 to 100 (as we believe this is a range that people are familiar with).

Research has shown that, with feedback on each trial, people can learn these scales quite accurately (King & Lockhead, 1983; Koh & Meyer, 1991; Koh, 1993; West & Ward, (1994); Marks, Galanter, & Baird, 1995). However, we have found that once the feedback is taken away, people start to drift off of the learned scale. Therefore, during the

test phase the learned scale is presented on every second trial followed by feedback, so that the form of the scale is constantly refreshed in memory. On the alternate trials, test stimuli, different from the learned stimuli, are presented without feedback. The observers are instructed to use the learned scale to respond to the test stimuli as well as the learned stimuli. They are also told that the response range of the test stimuli may be greater or less than the response range of the test stimuli.

This general approach was used in West et al (2000) and the results were compared to other psychophysical methods. In that study, the learned scale stimuli were 1000 Hz tones between 32 dB and 99 dB, spaced at 1 dB intervals. The learned scale responses were numbers from 1 to 100 related to the stimulus magnitudes by a power function with an exponent of 0.600 (taken from the International Organization for Standardization, 1959). The test stimuli were 65 Hz tones and light brightness. The results, a full discussion of the psychophysical meaning of the results, and a comparison to other methods is presented in West et al (2000). Here we will just point out that constrained scaling produced very low levels of inter-observer variability compared to ME and CMM. Furthermore, the only method that we could find that produced similar low levels of inter-observer variability was conjoint measurement as applied to combined pairs of tones (Schneider, 1988). However, this methodology exploits the fact that, under the right conditions, loudness is additive for two tone combinations, which limits its application to auditory stimuli. It also requires a large number of trials.

Scaling Video Frame Rates

The results from West et al (2000) clearly demonstrated that training observers and using external means to constantly refresh their memory produces highly reliable scaling results. This indicates that arbitrary decisions about how to structure a scale and insufficient resources for maintaining the scale in memory are the primary source of inter-observer variability in direct scaling. However, it was still unclear how observers use the feedback to maintain a representation of the scale. We speculated that observers memorized a limited number of perceived magnitude/response pairs and interpolate to get responses in-between (see Ward & West, 1988, for an example of people using this strategy in a similar type of task). If this is the case then constrained scaling should work if the observers are only supplied with feedback on a limited number of S/R pairs instead of many pairs covering the whole range (as in West et al 2000).

We applied this methodology in a study designed to look at the effect of content type on the perception of frame rate in video clips. Specifically, we were interested in whether or not speed of movement in the clip alters the perception of frame rate. To do this we began with a pilot study using magnitude matching. Magnitude matching is a version of ME in which two different stimuli are alternately presented in the same scaling task (J. C. Stevens & Marks, 1980). In this case we used a fast paced video clip and a slow paced video clip. The results, averaged across observers, indicated that the exponent for frame rate was approximately 0.90. No

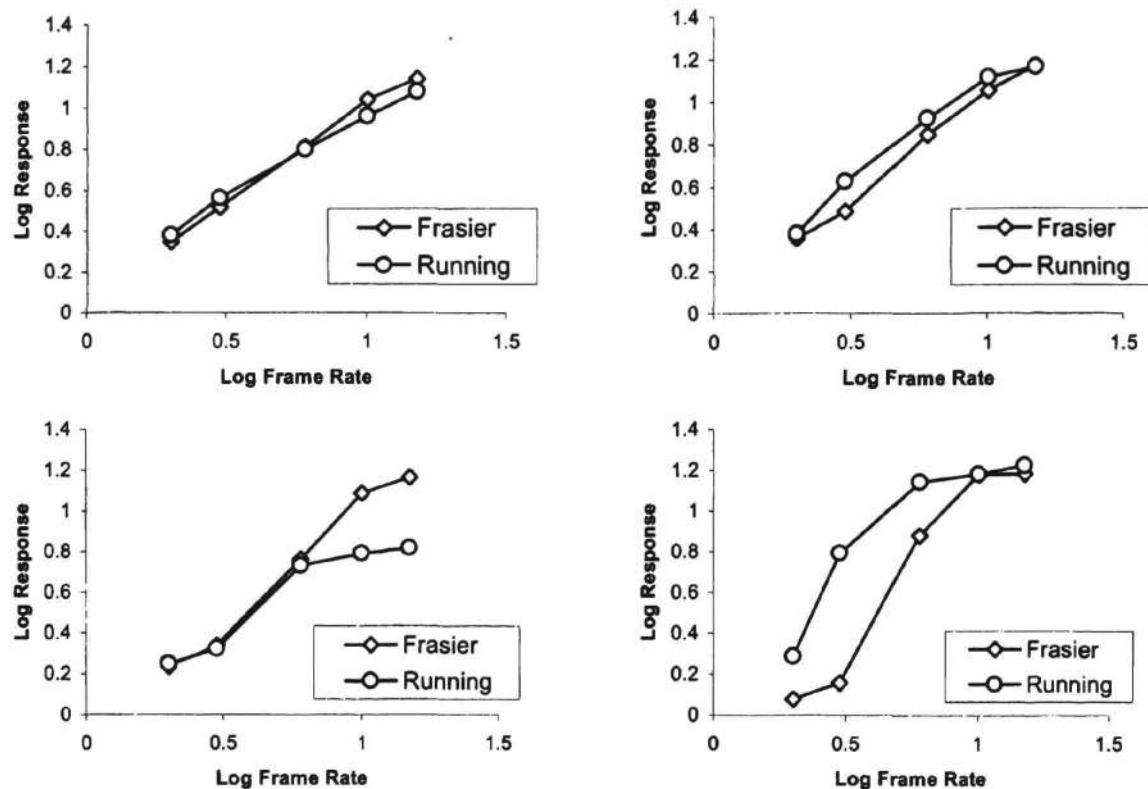

Figure 1. Psychophysical functions for four representative observers. The top row shows two observers who obeyed the power law and the bottom row shows two observers who deviated from it

significant effects for content were found (Boring, West, & Dillon, 2000).

For the constrained scaling experiment we used only five stimulus levels for training (2, 3, 6, 10, and 15 frames per second). Observers were taught, using feedback, to respond to these frame rate levels according to a power function with an exponent of 0.90. The observers were given 50 trials to learn the scale and the stimuli were presented randomly. The content of the video clip was moderate in speed (medium speed hip hop dancing).

During the test phase, the observers were instructed that the same hip-hop clips would be presented with feedback on every second trial, and that on the alternative trials a different video clip would be presented. The Observers were told to respond to the other clip using the same scale they learned for the hip-hop clip, but that the frame rate levels would not necessarily be the same and that there would be more than five versions of the new clip. This was actually not true; the test stimuli were generated using the same frame rate levels as the learning stimuli. However, the observers did not know this as the stimuli were spaced less than one JND (just noticeable difference) apart. We mislead

our observers so that they would be open to responding with the whole range of responses. The observers all completed two test phase sessions, one using a fast content clip (children running) and one using a slow content clip (a clip from the Fraser show of Fraser talking). The order of the sessions was counterbalanced and another 50 trials of training were presented in-between. All stimuli were presented in random order.

Results

As in West et al (2000), we found that constrained scaling did not produce outliers, so we used mean response values for scaling the responses instead of medians. From a visual inspection of the graphed functions from the test phase trials it was clear that four observers produced functions with relatively large nonlinear trends (see Figure 1). This is actually not uncommon in ME (Luce, & Mo, 1965). The normal procedure would be to throw them out or to average across them, along with the functions of the other observers. However, since we are interested in individual differences, we note that these four were less able than the other

observers to exploit the external scaling aids offered by constrained scaling. This indicates that individual differences in strategy, cognitive ability, and/or effort still play a role. Since these deviations were not unusually large by ME standards we analyzed the data both with them in and with them out. The remaining six observers produced functions that could reasonably be treated as linear (see Figure 1).

West et al reviewed 14 studies that provided individual observer results for ME and CMM, and calculated the standard deviation divided by the mean for the individual exponent values from each study. As a basis for comparison we took these values and calculated the mean, which was 0.333, the standard deviation, which was 0.080, and the 0.05 confidence interval, which was plus or minus 0.042. Even with the four linearly deviant observers included, the mean of the individual exponent values divided by the standard deviation was 0.190 for the Fraser clip and 0.150 for the children running clip, significantly lower than what would be expected with ME or CMM. Without the four deviants included, the mean divided by the standard deviation was 0.076 for the Fraser clip and 0.047 for the children running clip. These values were similar to the mean divided by standard deviation values found by West et al (2000) using constrained scaling (these values were 0.045, 0.066, and 0.152).

Also, because of the low variability we were able to detect a small but significant difference in exponent values both with ($P < 0.01$) and without ($P = 0.01$) the four linearly deviant observers, indicating that the exponent values for the slower video were higher than the exponent values for the faster video. This finding illustrates the advantage of having more precise ways of measuring perceived magnitudes (note, since the purpose of this paper is to examine the cognitive aspects of scaling, we will not discuss why this difference might exist).

Discussion

These findings replicate the West et al (2000) finding that augmenting the cognitive abilities of the observer can significantly reduce inter-observer variability and, more generally, supports the four theoretical assumptions behind constrained scaling (see above). The results also support the hypothesis that people can maintain scales in memory by memorizing a limited number of S/R pairs. By providing support to remember five S/R pairs we significantly reduced inter-observer variability to a level comparable to that found in West et al (2000), who provided feedback for a large number of responses. Other strategies may also be possible but, at the very least, this result shows that providing support for remembering a small number of S/R pairs can provide a significant advantage.

In terms of strategy, examining the actual responses that the observers made revealed that they took a category scaling approach. Two observers used the five R values they had learned almost exclusively. The other observers added only a few new R values and some stopped using one or two of the learned R values. The new R values also tended to be used as categories, that is, they were used repeatedly. This was quite different from the West et al (2000) observers who

responded with a wide range of R values. From this it would appear that observers prefer to continue using a response strategy that resembles the one they were trained on. This may be due to observers inferring that the number of test stimuli will be similar to the number of learning stimuli, or it may be that teaching them to respond in a particular way creates cognitive structures that are not amenable for doing the task in other ways.

The fact that observers were able to respond accurately using a category scaling strategy, on a scale that was determined using ME, suggests that training and providing feedback to observers eliminates the factors that cause category scaling to produce different results from ME. This result is quite promising as it suggests that providing external support for the scaling process can wipe out methodologically induced biases.

Conclusions

These results provide compelling evidence that cognitively augmenting observers can substantially increase the reliability of psychophysical scaling, which is particularly important for measuring and studying individual differences and small group differences (as in this study). We also believe that this approach will eventually provide a means for assessing the validity of the scales as well. This is based on the assumption that the further a learned scale is from the natural scale, the more cognitive resources will be required to maintain the mapping (C) from P to R (for some evidence of this see Marks, Galanter, & Baird, 1995; West et al, 2000). To improve further we need to better understand the strategies available to observers, and how to more effectively intervene to support the scaling process. Eventually, we hope that this approach will lead to psychophysical measurement techniques that have the same unambiguous status as physical measuring techniques.

Adapting to a Response Deadline in Categorization

A. J. Wills (a.j.wills@ex.ac.uk)

School of Psychology, University of Exeter,
Perry Road, Exeter. EX4 4QG. England

Abstract

The effect of a response deadline on categorical decisions was investigated. Time available for response was manipulated in the test phase, along with stimulus difficulty. Effects of these manipulations were observed in response accuracy, and in the mean, standard deviation and skew of the reaction times. The effects observed demonstrate that participants responded to the deadline in an adaptive manner - reducing their reaction time to long-latency decisions whilst leaving short latency decisions relatively unaffected. A simple connectionist model of categorical decisions (Wills & McLaren, 1997) is shown to account for this behavior.

Introduction

Categorization is a basic and essential cognitive function. Our ability to engage it has been well studied, and a number of different theories of the underlying processes have been proposed (e.g. Ashby & Gott, 1988; Gluck, 1991; Nosofsky, 1986; Nosofsky, Palmeri & McKinley, 1994). At first, attempts to quantitatively fit models of categorization to empirical data concentrated on categorization accuracy. However, in recent years, models which have the potential to predict reaction time distributions in categorization have been developed and evaluated (e.g. Ashby, 2000; Maddox, Ashby & Gottlob, 1998; Lamberts, 2000; Nosofsky & Palmeri, 1997; Wills & McLaren, 1997).

This paper focuses on the effects of imposing a response deadline on a) participants' response accuracy and b) the nature of their reaction time distributions. It has been known for some time that categorical decisions made under time pressure may be different to those made without time pressure (eg. Smith & Kemler Nelson, 1984). More recently, this avenue of research has been developed by investigation of the effects of time pressure with more complex stimuli (e.g. Lamberts, 1995; Palmeri & Blalock, 2000) coupled with formal modeling of the results found (e.g. Lamberts, 1995).

It is worth considering Lambert's (1995) study in a little more detail as it provides one motivation for the current work. At one level, the results found are intuitive. In these experiments, Lamberts employed a simple deadline procedure. Participants first learned, in the absence of time pressure, to categorize artificial stimuli (schematic faces) into two categories. Following this training, participants had to categorize test stimuli before a given deadline (e.g. 1600ms from stimulus

onset). Failure to respond in time resulted in an error tone, followed by the presentation of the next stimulus. Participants were informed about the time available for response, which changed at regular intervals. In one experiment, the deadlines employed were 600ms, 1100ms, 1600ms and no deadline. Participants were less accurate at shorter deadlines. Interestingly, the effect was stimulus specific, with some stimuli being considerably more affected by time pressure than others. Lamberts proposed a particular formal model of this effect (the "Extended Generalized Context Model" or EGCM, Lamberts, 1995) and showed that it provided a good fit to the accuracy data.

Time pressure and reaction time

Lamberts' experiments reveal another result. In his experiments, categorization in the absence of a response deadline takes approximately 1500ms (Lamberts, 1995, experiment 2). As the stringency of the deadline increases, so the mean reaction times decrease, with categorization under a 600ms deadline taking about 450ms. In other words, categorical decisions appear to take considerably less time when there is time pressure than when there is not. This is, of course, intuitively obvious. The interest, from the perspective of the current paper, is that there seem to be at least three distinct reasons why it might happen. When considering the following, it is important to remember that the descriptions relate to observed reaction time distributions - they are not statements about underlying process:

Non-selective adaptation: The participant reacts to the imposition of the deadline in a manner that decreases all reaction times in the distribution by a fixed amount. As a consequence, mean of the distribution will drop, but the standard deviation and skew will be unaffected.

Selective, linear adaptation: The participant reacts to the imposition of the deadline in a manner which decreases all reaction times in the distribution by a fixed factor (i.e. $RT_{\text{deadline}} = f \times RT_{\text{no deadline}}$). As a result, the mean and standard deviation of the distribution will drop, but the skew will be unaffected.

Selective, non-linear adaptation: The participant reacts to the imposition of the deadline in a way that cannot be characterized as non-selective, or selective, non-linear, by the definitions above. Changes in the mean, standard deviation, and skew of the distribution may all be observed.

Demonstrating adaptation to a deadline

It therefore seems clear that to distinguish between these explanations, one must estimate changes in the mean, standard deviation and skew of the reaction time distribution produced by imposition of a deadline. Whilst the experiment reported in this paper is by no means the first to investigate the effects of a deadline on categorization accuracy and reaction time, previous work has had at least one of the two following limitations:

Missing data artifact

In a number of studies (e.g. Lamberts, 1995; Lamberts & Brockdorff, 1997; Palmeri & Blalock, 2000) it is possible that the changes observed are an artifact of the data collection procedure. In a response deadline procedure, longer-than-deadline responses typically result in a "time out" error and hence no data about reaction time is available for that trial. As a direct consequence, mean response time is lower than it would have been without a deadline. The same problem applies to studies that compare two different deadlines. In experiments where percentage of time-outs is reported by condition, they can be seen to increase as the response deadline becomes more stringent.

One solution to this problem is to use a "response signal" procedure (e.g. Lamberts, 1998) where participants are instructed to respond as soon as possible after they get a signal to do so. Another solution (see e.g. van Zandt, Colonius & Proctor, 2000) is to provide a "too slow" signal after the response has been made.

A third possibility is to use the standard response deadline procedure, but only evaluate responses that fall below a certain percentile of the reaction time distribution (with time-outs being considered as the slowest trials). The largest number of time-outs made at any level of time pressure, by any participant, to any of the test stimuli, determines this percentile. For all conditions and stimuli, only responses that fall below that fixed percentile are considered. It is therefore important to keep the percentage of time-outs low so a reasonable amount of data is still available for analysis. It is this final possibility that is employed in the current study.

Insufficient information

The three possibilities for adaptation outlined above can only be distinguished if one has estimates for the mean, standard deviation, and skew of the reaction time distributions. Recently, many studies of categorization have begun to report reaction time distributions in detail (e.g. Maddox & Ashby, 1996). However, categorization studies that employ time pressure as a manipulation tend to concentrate on categorization accuracy, and may

also report mean reaction times. Data from different tasks, such as perceptual matching, show that the mean, standard deviation, and positive skew all reduce in response to increasing time pressure (van Zandt et al., 2000).

Given the absence of appropriate information, it was decided to perform a short empirical study that would have the potential to discriminate between the three types of adaptation to a response deadline which have been outlined. This is followed by a demonstration that a particular model of categorical decisions (Wills & McLaren, 1997) can mimic the results found. Implications of both the empirical and the theoretical investigations for categorization research are then discussed.

Experiment

The current experiment had two phases. In the training phase, participants were presented with novel, abstract stimuli paired with either the category label "A" or the category label "B". In the test phase that followed, participants had to decide the category membership (A or B) of unlabelled stimuli either without time pressure, with a 2500ms time limit for each decision or with a 1000ms time limit for each decision (a between-participants manipulation).

Whilst these deadlines may appear relatively lax compared to the reaction times observed in some classification tasks, previous work (e.g. Wills & McLaren, 1997) indicates they represent a fairly high level of time pressure for participants with relatively little experience of the complex stimuli employed.

Method

Participants and apparatus

The participants were 44 adults, mainly undergraduate students. The experiment was in two different, quiet cubicles on two Acorn RISC PC computers, with 14" color monitors. Participants sat 1 meter from the screen.

Stimuli

Each stimulus was a collection of twelve different small pictures (hereafter "elements") in a 4.5cm by 3.5cm rectangle outline, arranged on an invisible four-by-three grid (see Figure 1 for an example stimulus). Every stimulus contained twelve elements drawn from the pool of thirty-six elements we have used in previous experiments (see Jones, Wills & McLaren, 1998, p.37). At the beginning of the experiment, and separately for each participant, 12 elements from the pool were randomly designated as category A elements, and a different 12 as category B elements. The remaining 12 elements were not used for that participant.

Figure 1: An example stimulus

Training stimuli

Sixty training stimuli (thirty from each category) were created for each participant. Each training stimulus was constructed by starting with all 12 elements characteristic of a particular category (e.g. category A elements for a category A training stimulus). Then, each element in the training stimulus underwent a 10% chance of being replaced by an element chosen from the other set (e.g. replaced by a category B element in the case of a category A training stimulus). Choice of replacement elements was random within the constraint that no element could occur more than once in any given stimulus. The position of elements within a stimulus was randomly determined for each stimulus presented, with the constraint that exactly one element occurred at each location in the four-by-three grid.

This method of stimulus construction produces training examples which are composed predominately of elements characteristic of a particular category but which also exhibit considerable variability.

Test stimuli

Test stimuli were designed to vary in difficulty of categorization. Given the nature of the training stimuli, the correct response to a test stimulus is to categorize it as an "A" if it contains more A elements than B elements, and as a "B" otherwise. A number of previous experiments have demonstrated that as the difference between the number of A elements and the number of B elements increases in a stimulus of this type, the probability of a correct classification also increases (Jones et al, 1998; Wills & McLaren, 1997). Test stimuli in this experiment are therefore described in terms of their difference scores (the absolute value of the number of A elements minus the number of B elements).

All stimuli contained twelve elements, so there are seven possible difference scores and hence seven levels of difficulty. The seven difference scores are 12, 10, 8, 6, 4, 2 and 0, which are denoted as having a difficulty level of 1,2,3,4,5,6 and 7 respectively. Twenty examples at each of the first six levels of difficulty were created for each participant. The specific elements used to create each test stimulus were chosen randomly within the constraint provided by the difference score, and the constraint that stimuli in which category A elements were more numerous than category B elements should occur with the same frequency as stimuli in which category B elements were more numerous than category A elements. As in the construction of the

training stimuli, the position of elements within a test stimulus was randomly determined, and no element was allowed to occur more than once in any given stimulus.

Ten examples of stimuli with a zero difference (difficulty level 7) were also generated for each participant. However, as there is no correct answer for such stimuli, performance on them is not analyzed in this paper.

Procedure

Participants were allocated to one of three groups that differed only in the time allowed for decision in the test phase. These groups are referred to hereafter as the *1000ms*, *2500ms* and *No-deadline* groups. Sixteen participants were allocated to the 1000ms group, sixteen to the 2500ms group, and twelve to the no-deadline group.

The sixty training stimuli were presented sequentially and in a random order. Each example was presented for five seconds in the center of the monitor accompanied by the appropriate category label (presented as a large capital A or B in an outline rectangle immediately to the right of the stimulus). The stimulus and the category label were then replaced with mid-gray rectangles that stayed on the screen for two seconds and were followed by the next example. Participants were not required to respond in any way in this first phase of the experiment but were asked to concentrate on the examples shown as they would later be asked to classify new, unlabelled examples. This training procedure has proved effective for stimuli of this type in a number of other experiments (Jones et al, 1998; Wills & McLaren, 1997).

The training phase was followed immediately by the test phase. There were 130 stimuli in this phase (see "Stimuli" section) which, again, were presented sequentially and in a random order. Participants classified each stimulus as an "A" or a "B" by pressing either the "X" or ">" key on the computer keyboard. The allocation of keys to responses was counter-balanced across participants.

In the 1000ms and 2500ms conditions, participants were told that they only had 1 second or 2.5 seconds to make each decision. If they did not respond within this time interval, the stimulus was replaced by the phrase "TIME OUT!" in 2cm high letters. After a five second count-down and a two-second pause, the next stimulus was presented. This time-out procedure was designed to be as salient as possible in order to keep the total number of time-outs low.

Results

Accuracy and mean reaction time data from the no-deadline condition have been reported previously (Wills & McLaren, 1997). All other data are novel.

In the 2500ms condition, 2.87% of trials were timed-out. The figure was 4.84% in the 1000ms condition.

Whilst both rates are relatively low, there were significantly more time-outs in the 1000ms condition, $t(30) = 2.41$, $p < 0.05$. All participants in this experiment made at least sixteen responses before the deadline at each level of stimulus difficulty. Therefore the four slowest responses made by each participant at each level of stimulus difficulty were disregarded in the following analyses (see Introduction for an explanation of this procedure). Time-out trials were counted as the slowest possible responses. For the remaining data, the accuracy, and the mean, standard deviation and skew, for each level of stimulus difficulty and for each participant were calculated.

This data set was subjected to a series of mixed-model ANOVAs, with one within-participants variable (Difficulty, 6 levels) and one between-participants variable (Deadline, 3 levels). A significance level of .05 was set for all analyses. Figures 2 and 3 summarize the data set by providing across-participant averages.

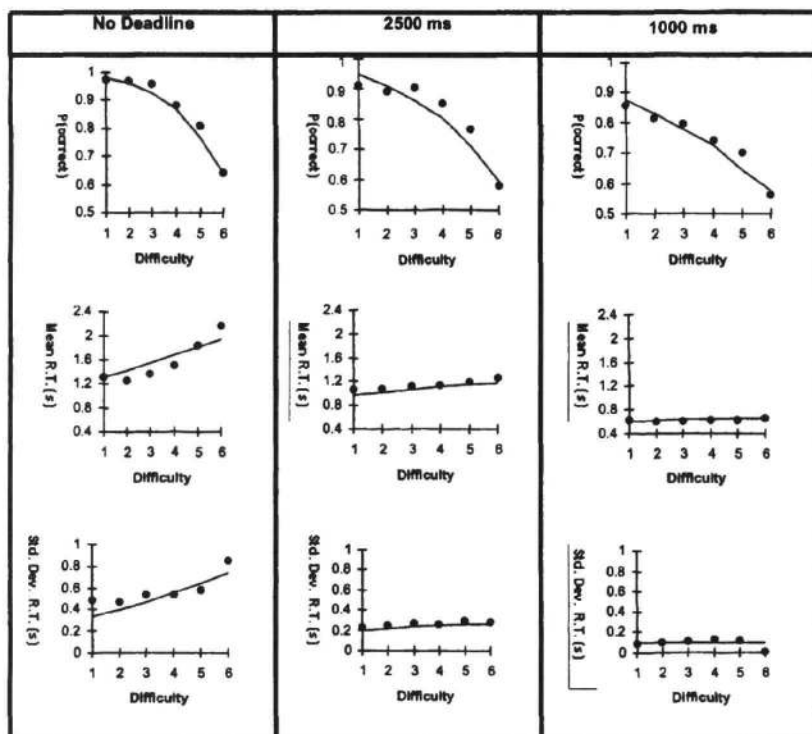

Figure 2: Accuracy, mean reaction time, and standard deviation of reaction time as a function of stimulus difficulty (arbitrary units) and response deadline (milliseconds).

Filled markers indicate empirical data. Lines indicate modeling results.

Figure 3 also averages across stimulus difficulty because (as will be seen in a moment) there was no significant effect of stimulus difficulty on skew.

Response accuracy was adversely affected by both stimulus difficulty, $F(5, 205) = 48.1$, and deadline $F(2,$

41) = 6.45. These two factors did not interact significantly, $F(10, 205) < 1$. Mean reaction time increased with stimulus difficulty, $F(5, 205) = 20.19$, and decreased with time pressure, $F(2, 41) = 12.92$. The effect of stimulus difficulty was less pronounced with increasing time pressure, as evidenced by a significant interaction term, $F(10, 205) = 9.32$.

The standard deviation of reaction times increased with stimulus difficulty, $F(5, 205) = 5.77$, and decreased with increasing time pressure, $F(2, 41) = 17.36$. The effect of stimulus difficulty was less pronounced with increasing time pressure, as evidenced by a significant interaction term, $F(10, 205) = 8.45$.

The skew of reaction times decreased with increasing time pressure, $F(2, 41) = 19.52$. However, stimulus difficulty had no significant effect, $F(5, 205) = 1.31$, and the interaction term was non-significant also, $F(10, 205) < 1$. The no-deadline condition shows significantly positive skew, $t(11) = 5.06$, whilst the 1000ms condition shows significantly negative skew, $t(15) = 2.76$. The 2500ms condition showed no significant skew, $t(15) = 0.98$.

Modeling

Wills & McLaren's winner-take-all (WTA) model, like many process models of categorization, assumes that the evidence a presented stimulus is the member of a particular category is represented by a single number or *magnitude term*. In this simulation, the magnitude term for category x (denoted v_x) is $M \times c$, where c is the number of category x elements the presented stimulus contains, and M is a free parameter. Such a relationship sufficiently describes the output of a feature-based, single-layer, delta-rule network taught to classify the stimuli (see Wills & McLaren, 1997 for more details).

The model is illustrated in Figure 4. A single unit represents each category. The magnitude terms for each category are passed to these units as input activation. The output activity of each unit is a function of the total

Figure 3: Skew of reaction times as a function of response deadline (milliseconds).
input it receives. Specifically, the output activation of unit i on update c is determined by

$$o_{i,c} = \frac{o_{i,c-1} + En_{i,c}}{1 + En_{i,c} + D} \quad o_{i,c} = \frac{o_{i,c-1}}{1 - En_{i,c} + D}$$

(where $n_{i,c} > 0$) (where $n_{i,c} \leq 0$)

$n_{i,c}$ is the total input to unit i on update c and E and D are constants representing the rate of excitation and decay within the unit.

In addition to the magnitude-term inputs, each unit has a fixed excitatory connection to itself and fixed inhibitory connections to other units. These connections cause the units to "compete" with one another until only one has non-zero activation. Grossberg (1976), and many others since, have employed similar, neurally-inspired decision-making systems.

The total input to a unit i on update c is given by

$$n_{i,c} = r_{i,c} + o_{i,c-1} - \sum_{j \neq i} o_{j,c-1}$$

where $r_{i,c}$ is the noisy input produced by the magnitude term v_i . The noise in these particular simulations had a range of $+N$ to $-N$, and a rectangular distribution. Superimposed on this noise is the constraint that $r_{i,c}$ cannot exceed one or fall below zero.

The first unit to produce an activation greater than S is assumed to cause the execution of its corresponding response. The number of cycles the unit takes to exceed S represents decision latency, with each cycle representing exactly T seconds.

The model employed includes a number of simplifications, including the assumption that noise is rectangular and that non-decisional components of the categorization process take a fixed T_{res} seconds. Neither simplification is central to the operation of the model - similar predictions can be derived from a model with a variable T_{res} and Gaussian noise. However these simplifications have the advantage of considerably speeding the search of parameter space.

The model described above has seven parameters - N , E , D , M , S , T and T_{res} . The basis of the model's predictions is that time pressure reduces the value of S , so S was assigned a different value for each of the three between-participant conditions of the experiment. In all previous applications of the model, it has been assumed

that $E = 2D$, and this assumption is continued in the current simulation. T is not a parameter of the model in any important sense, as its only purpose is to convert from one arbitrary unit of time (cycles) to another (seconds). Hence, model fitting involves the manipulation of seven free parameters, from which predictions for 57 data points are to be derived.

Model fitting proceeded via a grid-search procedure. The range and steps of the parameters were N (0.1→3, step 0.1), E (0.01→0.05, step 0.01 and 0.05→0.5, step 0.05), M (0.01→0.08, step 0.01), and S (0.3→0.7, step 0.05) for each of the three S parameters, with the constraint that S did not increase as response deadline decreased. 10,000 decisions were simulated for each permutation of parameters and for each stimulus difficulty level. The cycles-to-decision in each set of 10,000 decisions were then placed in rank order, and the 2,000 slowest decisions discarded (in order to mimic the data deletion performed on the empirical data).

This collection of simulated decisions was then employed to produce a set of predictions for each of the permutations of the parameters N , E , M and the three S parameters, S_{ND} , S_{2500} and S_{1000} . The relationship between cycles-to-decision and seconds was then estimated for each set of decisions via linear regression

Figure 4: The winner-take-all model

of the 18 empirical mean reaction times to the 18 mean cycles-to-decision. The gradient of the line gives the conversion factor T whilst the intercept provides the value for T_{res} .

Once T and T_{res} were determined for a set of predictions, they were employed to convert each of the 180,000 simulated decision latencies into seconds. Calculations of mean reaction time, reaction time standard deviation and reaction time skew for each stimulus difficulty level in each of the three conditions were then performed using standard formulae.

Scaled root mean square deviations (SRMSD) were used to assess closeness of fit. Scaling was performed by multiplying each empirical data point and each prediction by a factor s . SRMSD was calculated separately for accuracy, mean RT, RT standard deviation, and RT skew predictions. The scaling factors employed were 2, 0.5, 1 and 1 respectively. Total SRMSD was taken to be the sum of these four SRMSDs. The set of parameters providing the best overall fit were as follows N : 2.6, E : 0.03, M : 0.04, S_{ND} : 0.55, S_{2500} : 0.50, S_{1000} : 0.40, T_{res} : 0.033. This is the fit shown in Figures 2 and 3. One cycle of the model was estimated by linear regression to be 0.014 of a

second. Cycles-to-decision predicted over 95% of the variance of mean reaction times in this regression ($r^2 = 0.953$). The SRMSD for accuracy predictions was 0.061, for mean reaction time it was 0.047, for reaction time standard deviation it was 0.062 and for reaction time skew it was 0.063.

Discussion

Imposition of a response deadline decreased the mean, standard deviation and skew of reaction times in a categorization task. From this information about the distribution, one can conclude that these participants adapted to the response deadline in a selective, non-linear manner (as defined in the Introduction). This is a result which, if found to be general, would need to be accommodated by formal models of categorical decisions. The fact that one of the reaction time distributions to be fit is negatively skewed might be considered as a particular source of concern, as categorization have almost uniformly been fit to distributions with some degree of positive skew in the past.

In the space available, it was not possible to evaluate whether all current models of categorical decision have the potential to accommodate the results found. Instead, it was demonstrated that one particular model of categorical decisions (Wills & McLaren, 1997) can mimic the pattern of results found. Wills & McLaren's model is (in approximate terms) a connectionist implementation of a random-walk process (e.g. Laming, 1968). As such, it follows the same basic principles as a variety of other accounts of categorical decision, including stochastic forms of decision-bound theory (Ashby, 2000), extensions of EGCM that can model reaction times (Lamberts, 2000), and Nosofsky & Palmeri's (1997) exemplar-based random walk model. It therefore seems likely that many contemporary models of categorization are capable of accounting for the sort of adaptation to a response deadline observed in this study.

Abstract

This paper proposes a new model of causal meaning, the Vector Model, which formalizes a model of causation based on Talmy's notions of force dynamics (Wolff, Song, & Driscoll, 2002). In the Vector Model, the concepts of CAUSE, ENABLE and PREVENT are distinguished from one another in terms of force vectors, their resultant and the relationship of each force vector to a target vector. The predictions of the model were tested in two experiments in which participants saw realistic 3D-animations of an inflatable boat moving through a pool of water. The boat's movements were completely determined by the force vectors entered into a physics simulator. Participants' linguistic descriptions of the animations were closely matched by those predicted by the model given the same force vectors as those used to produce the animations. Our model may have implications for the semantics of causal verbs as well as the perception of causal events.

Introduction

This research investigates people's notions of causation as reflected in their use of causal verbs. We approach this problem by formulating a model of causal meaning that defines causal concepts in terms of relationships between force vectors, their resultant and a target position vector.

We begin by noting two key problems for models of causal meaning. First, such models must be able to distinguish the concept of CAUSE from the concept of ENABLE. We say, for example, the wave (and not the keel) *caused* the sailboat to rock, while the keel (and not the wave) *enabled* the sailboat to rock. The precise way in which these two notions differ has been difficult to specify. Contributing to this difficulty is the fact that the two concepts cannot be distinguished in terms of necessity or sufficiency (Cheng & Novick, 1991; Goldvarg & Johnson-Laird, 2001). In the above example, neither the wave nor the keel alone is sufficient, but both may be necessary for the boat's rocking to occur. Several solutions to this challenge have been proposed, but most have not escaped criticism (see Cheng & Novick, 1991; Goldvarg & Johnson-Laird, 2001; Wolff, Song, & Driscoll, 2002).

A second key problem for models of causal meaning concerns how the concept of CAUSE is represented in expressions that refer to specific instances of causation. Many models of causation define causation in terms of probabilities (e.g., Cheng, 1997; Cheng & Novick, 1991; Glymour, 2001). Such models are well suited for explaining the meaning of generic statements of causation, that is, statements about what is typically the case in multiple occurrences of a particular event, as in *Heavy snowmelt causes rivers to flood*. What these theories do not handle well are expressions that refer to a single instance of causation, as in *The heavy snowmelt caused the Colorado to flood*. Sentences describing single instances express what is definitely true of a particular event, not what is typically true of many. Moreover, such sentences are incompatible with the non-occurrence of the result (e.g., flooding), but if causation is inherently probabilistic, such non-occurrences cannot be strictly ruled out (Goldvarg & Johnson-Laird, 2001).

In some theories of causation, the concept of CAUSE is defined in such a way that it can be used in descriptions of singular causation. For example, according to Michotte (1963), causation is inferred from the perception of a transfer of motion from one ball to another—an "ampliation of motion" (p. 143). A related proposal is that CAUSE is inherently based on the idea of force and that the occurrence of CAUSE involves a mechanism by which this force is transmitted (Ahn & Kalish, 2000; Shultz, 1982). While these theories specify properties that could be predicated of a single event (and are highly related to the proposal we make in this paper), they do not provide us with a clear solution to the first problem of causal meaning: how the notion of CAUSE might be distinguished from the notion of ENABLE.¹ Both CAUSE and ENABLE presumably involve the transference of force.

In this paper, we propose a model of causal meaning that addresses these two problems. This model represents a formalization of the Force Dynamic Model described in Wolff, Song and Driscoll (2002; also Wolff & Song, 2001). In the next section, we describe

¹ Counterfactual theories of causation face related problems (see Spellman & Mandel, 1999)

the Force Dynamic Model as well as some of the empirical evidence in support of it. We then turn to a description of its formalization.

The Force Dynamic Model of Causation

A theory of force dynamics was first proposed by Talmy (1988), and has been elaborated by several other researchers (Jackendoff, 1991; Kemmer & Verhagen, 1994; Pinker, 1989; Robertson & Glenberg, 1998; Siskind, 2000; Verhagen & Kemmer, 1997). From a force dynamic perspective, the concept of CAUSE is one member of a family of concepts that include the concepts of ENABLE and PREVENT, among others. With each of these concepts, there are two key players: an affector and a patient.² Differences among the concepts are captured in terms of various patterns of tendency, relative strength, rest, and motion.

The Force Dynamic Model specified in Wolff, Song and Driscoll (2002) combines two of Talmy's (1988) core dimensions (Tendency & Result) with a dimension suggested by Jackendoff (1991).³

Table 1: The Force Dynamic Model's representations of CAUSE, ENABLE, & PREVENT

	Patient Tendency for Result	Affector-Patient Opposition	Occurrence of Result
CAUSE	N	Y	Y
ENABLE	Y	N	Y
PREVENT	Y	Y	N

As shown in Table 1, this model specifies that the concepts of CAUSE, ENABLE, and PREVENT can be captured in terms of 1) the tendency of the patient for the result, 2) the presence of opposition between the affector and patient, and 3) the occurrence of the result. In causing situations (see 1a), for example, the tendency of the patient, the boat, is not for the result, healing. But because the tendency is opposed by the affector, the result, i.e., healing, occurs.

- (1) a. The blast caused the boat to heel.
- b. Vitamin B enables the body to digest food.
- c. The rain prevented the tar from bonding.

In enabling situations, as in (1b), the tendency of the patient, the body, is for the result, to digest food. This tendency is not opposed by vitamin B. Rather, vitamin B assists in the realization of this tendency, which leads to the occurrence of a result. In situations involving preventing, as in (1c), the tendency of the patient, the tar, is towards the occurrence of the result, bonding, but

this tendency is opposed and blocked by the affector, and as a consequence, the result does not occur.

Evidence in support of the Force Dynamic Model
As indicated in Table 1, the Force Dynamic Model predicts that each concept shares one feature in common with each other concept: ENABLE and PREVENT both involve patients with a tendency for the result; CAUSE and PREVENT both involve opposition; and CAUSE and ENABLE both lead to results. The model implies, then, that the three concepts should be equally similar in meaning. Therefore, if we were to plot these concepts in a similarity space in terms of the verbs that encode them, they should reside roughly equally distant from one another. In fact, this is exactly what we found when we asked people to sort 48 sentences from the British National Corpus that contained 23 periphrastic causative verbs (i.e. verbs that pattern syntactically and semantically like the verb *cause*, e.g., *make*, *enable* and *prevent*) and submitted their sorts to a multidimensional scaling program⁴ (Wolff et al., 2002).

Figure 1: MDS solution of periphrastic causative verbs

As Figure 1 shows, the periphrastic causative verbs in English fall into three categories: a CAUSE category that includes the verbs *cause*, *force*, *get*, *make*, *set* and *stimulate*, an ENABLE category that includes the verbs *allow*, *enable*, *help*, *leave*, *let*, and *permit*, and a PREVENT category that includes the verbs *block*, *hinder*, *hold*, *impede*, *keep*, *prevent*, *protect*, *restrain*, *stop*. Importantly, the clusters associated with these three concepts reside roughly equally distant from one another, just as predicted by the Force Dynamic Model. We have replicated these results for specific and generic statements of causation. These results, along with several rating studies, lead us to believe that the Force Dynamic Model captures the primary semantic dimensions underlying the periphrastic causative verbs, and the verb *cause* in particular.

² We use the more familiar terms affector and patient instead of antagonist and agonist as originally used in Talmy (1988).

³ In Talmy (1988) nearly all interactions involve opposition while in Jackendoff (1991) this parameter is allowed to vary.

⁴ Multidimensional scaling is a procedure that locates items in space so that their distances in that space reflect as closely as possible their measured inter-item (dis)similarities.

The Vector Model of Causation

In the Vector Model, the notions of tendency, opposition (here, concordance), and result are represented as force vectors, their resultant and the relationship of each force vector to a target position vector. The model is described below for physical interactions in which the patient has no initial velocity. However, it is assumed that it could be extended to situations in which the patient does have an initial velocity (and, hence, momentum). It is also assumed that the model could be extended to cover non-physical kinds of causation (e.g., social, psychological).

In our description, all vectors are typed in boldface font; $\mathbf{P} \cdot \mathbf{T}$ denotes the dot product of the vectors \mathbf{P} and \mathbf{T} ; $\|\mathbf{P}\|$ denotes the magnitude of \mathbf{P} .

In the case of physical causation, \mathbf{A} represents a vector that specifies the force exerted on the patient by the affector; \mathbf{P} , any force produced by the patient to move itself, or in the absence of such a force, its weight (e.g., force pulling it toward the earth) and/or resistance to motion due to frictional forces; \mathbf{O} , the vector representing the summation of the remaining *other* forces acting on the patient⁵ and \mathbf{R} , the resultant force acting on the patient based on the vector addition of \mathbf{A} , \mathbf{P} and \mathbf{O} . An example configuration is shown in Figure 2.

Figure 2: Forces associated with the affector, \mathbf{A} , patient, \mathbf{P} , and other forces, \mathbf{O} , combine to produce a resultant force, \mathbf{R} , in the direction of a target.

The target's location is specified in terms of a position vector, \mathbf{T} . When the target and patient are points, \mathbf{T} simply begins at the patient and ends at the target, as shown in Figure 3.

Figure 3: The target's location is specified by a position vector \mathbf{T} .

In the more general case in which the target is represented by an area, the target's location would be specified by a set of real 1- or 2-dimensional position

⁵ The contribution of other forces, \mathbf{O} , might include forces whose entities could serve as affectors or patients in other interactions, as well as forces that might be used to distinguish between periphrastic causative verbs within a subcategory (e.g., *help* vs. *enable* vs. *allow* vs. *let*).

vectors, such that every vector from the patient's position to a point that could be considered a part of the target would be an element of that set.⁶

For this particular version of the Vector Model, we assume that all of the forces are constant with respect to time and space (i.e., $\partial/\partial t[\mathbf{Z}(x,y,t)] = \partial/\partial x[\mathbf{Z}(x,y,t)] = \partial/\partial y[\mathbf{Z}(x,y,t)] = 0$ where \mathbf{Z} is any force in this model), the patient has no initial velocity, and $\|\mathbf{P}\|$ and $\|\mathbf{T}\| > 0$.

The main dimensions of the Vector Model are defined in Table 2 for patients and targets that can be construed as points, and where $\|\mathbf{A}\| > 0$.

Table 2: Dimensions underlying the Vector Model

Dimension	Formal Definition
<i>Tendency</i> (of patient for the target)	Angle between \mathbf{P} and $\mathbf{T} = 0^\circ$
<i>Concordance</i> (of affector & patient)	Angle between \mathbf{A} and $\mathbf{P} = 0^\circ$
<i>Result</i>	Angle between \mathbf{R} and $\mathbf{T} = 0^\circ$

Rationale for the definitions *Tendency* - If the patient has a tendency for the target, then the direction of its force vector will coincide with the direction of the position vector \mathbf{T} . Thus, the angle between the vector \mathbf{P} and \mathbf{T} will be 0° . A test for this possibility can be stated with respect to the dot product of \mathbf{P} and \mathbf{T} . Specifically, when the patient has a tendency for the target, $\mathbf{P} \cdot \mathbf{T} = \|\mathbf{P}\| \cdot \|\mathbf{T}\|$,⁷ and when it does not, $\mathbf{P} \cdot \mathbf{T} < \|\mathbf{P}\| \cdot \|\mathbf{T}\|$.

Concordance - Concordance concerns the similarity of the force vectors associated with the affector and the patient. If the affector and patient exert forces (on the patient) in the same direction, then they are considered to be in concordance. In a similar fashion to tendency, concordance can be defined with respect to the dot product, but this time between \mathbf{P} and \mathbf{A} . Specifically, when the affector and patient are in concordance, $\mathbf{P} \cdot \mathbf{A} = \|\mathbf{P}\| \cdot \|\mathbf{A}\|$, and when they are not, $\mathbf{P} \cdot \mathbf{A} < \|\mathbf{P}\| \cdot \|\mathbf{A}\|$.⁸

Result - As with tendency and concordance, occurrence of a result can be defined in terms of the similarity between two vectors, but this time between \mathbf{R} and \mathbf{T} . When the angle between \mathbf{R} and \mathbf{T} is 0° , the result will occur, assuming all of the forces acting on

⁶ In the more general case in which the target is other than a point, we expect the definition of concordance must be changed to include a certain level of angular tolerance that would be based, in part, upon the relative size of the target and its proximity to the patient.

⁷ By definition of the dot product, $\mathbf{P} \cdot \mathbf{T} = \|\mathbf{P}\| \cdot \|\mathbf{T}\| \cdot \cos(\theta)$, where θ is the angle between vectors \mathbf{P} and \mathbf{T} . In the case where θ is 0° , the equation becomes $\mathbf{P} \cdot \mathbf{T} = \|\mathbf{P}\| \cdot \|\mathbf{T}\| \cdot \cos(0^\circ)$, which reduces to $\mathbf{P} \cdot \mathbf{T} = \|\mathbf{P}\| \cdot \|\mathbf{T}\|$.

⁸ When concordance is defined in terms of the dot product, it allows for a special type of concordance in which $\|\mathbf{A}\| = 0$. When $\|\mathbf{A}\| = 0$, the equality $\mathbf{P} \cdot \mathbf{A} = \|\mathbf{P}\| \cdot \|\mathbf{A}\|$ would hold, which may be representative of the kinds of situations referred to by the verbs *let*, *allow*, and *permit*.

the patient are constant with respect to time and space, as specified formally above. In terms of the dot product, the result will occur if $\mathbf{R} \cdot \mathbf{T} = \|\mathbf{R}\| \cdot \|\mathbf{T}\|$ and will not occur if $\mathbf{R} \cdot \mathbf{T} < \|\mathbf{R}\| \cdot \|\mathbf{T}\|$.

As with the Force Dynamic Model, CAUSE, ENABLE, and PREVENT are defined with respect to values along three dimensions, specified in Table 3, and share one feature with each other concept. Thus, both models predict that the three concepts should be equally similar to one another.

Table 3: The Vector Model's representations of CAUSE, ENABLE, & PREVENT

	Tendency of Patient for Target	Concordance of Affector & Patient	Result
CAUSE	N	N	Y
ENABLE	Y	Y	Y
PREVENT	Y	N	N

Testing the Vector Model of Causation

Beyond similarity, the Vector Model makes predictions about the vector configurations underlying verbs of causation. These predictions were tested in two experiments. Participants viewed 3D animations of an inflatable boat, the patient, moving across a shallow pool in relationship to a half-submerged cone, the target (see Figure 4). Each animation had two main parts. In the first, the boat moved from the side of the pool to the center. This part was included to establish the boat's tendency. In the second part, a bank of fans (i.e., the affector) started blowing. Thus, in the second part of every animation, the force produced by the boat itself was combined with the force exerted on the boat by the fans to give rise to a resultant force that determined the boat's direction and speed.

After watching an animation, participants chose among several possible linguistic descriptions. We predicted, per the Vector Model (and its computer implementation), that participants would choose a description containing the verb *cause* when the boat started moving away from the cone (Tendency = N), but was moved to the cone (Result = Y) by the fans blowing in a direction different from the direction of the boat (Concordance = N). We predicted that participants would choose a description containing the verb *help* (a type of ENABLE verb, see Figure 1), when the boat moved towards the cone (Tendency = Y) and ultimately reached it (Result = Y) when the fans blew in the same direction as the boat's direction of motion (Concordance = Y). We also predicted that participants would choose a description containing the verb *prevent* when the boat started towards the cone (Tendency = Y) but did not hit it (Result = N) because the fans blew it back or away from the cone (Concordance = N). Finally, we predicted that when none of the above

configurations were instantiated, participants would choose "none of the above." These predictions were tested for one- and two-dimensional interactions in Experiments 1 and 2, respectively.

Figure 4: Sample frame from an animation used in Experiment 2 that instantiated a "cause" interaction

Experiment 1

Method

Participants The participants were 18 University of Memphis undergraduates.

Materials Eight 3D animations were made from an animation package called Discreet 3ds max 4. The direction and speed of the boat was calculated by a physics simulator called Havok Reactor. In each animation the boat was initially located four boat-lengths away from the center of the pool. In the first half of the animation, the boat moved towards the center, ostensibly under its own power. Once the boat reached the center, the fans started blowing. The animation ended when the boat hit the cone or neared the side of the pool (~4 seconds total).

The top of Table 4 shows the direction and relative magnitudes of the force vectors associated with the affector and patient that were entered into the physics simulator. The affector, A, and patient, P, vectors were either in the direction of the target or in the opposite direction. The magnitude of the other forces vector, O, was set to 0. In half of the interactions, the affector vector was 1.7 times stronger than the patient (configurations 1-4), while in the remaining interactions the strengths were reversed (configurations 5-8).

Procedure The animations were presented in random order on Windows-based computers. After each animation, participants chose a sentence that best described the occurrence. All of the sentences were the same ("The fans ____ the boat to [from] hit[ting] the cone") except for the verb, which was either *caused*, *helped* or *prevented*. Another option was "none of the above." Participants indicated their answers by clicking a radio button next to their choice.

Table 4. The vectors configurations used in Experiment 1, along with associated predictions and results

Configuration	1	2	3	4	5	6	7	8
Affector (\rightarrow)								
Patient (\rightarrow)								
Target (T)								
Predictions	<i>Help</i>	<i>Cause</i>	<i>Prevent</i>	No verb	<i>Help</i>	No verb	No verb	No verb
Results								
<i>Cause</i>	11%	94%	-	-	6%	6%	-	-
<i>Help</i>	89%	6%	-	-	94%	-	11%	-
<i>Prevent</i>	-	-	100%	-	-	-	6%	6%
No verb	-	-	-	100%	-	94%	83%	94%

Results and Discussion

The predictions of the Vector Model were fully borne out by the results. The bottom of Table 4 shows the percentage of times people chose each of the four possible options for each of the vector configurations. Participants chose *cause*—as opposed to the other possible options—for the animation in which the boat first moved away from the cone but was later pushed back against it by the fans (configuration 2), a N-N-Y type of occurrence in terms of tendency, concordance and result (see Table 3), $\chi^2(3, N=18) = 62, p < .001$. Participants chose *help* when the direction of the boat and the fans was the same (1, 5), a Y-Y-Y type of occurrence, $\chi^2(3, N=18) = 116, p < .001$. Participants chose *prevent* when the boat moved towards the cone but was then kept from hitting it by the fans (3), a Y-N-N occurrence, $\chi^2(3, N=18) = 72, p < .001$. Finally, participants chose “none of the above” when the vector configurations did not map onto any one of the three main kinds of configurations, $\chi^2(3, N=18) = 237, p < .001$. Importantly, participants did not choose *prevent* whenever the boat missed the cone (4, 6, 8). Instead, *prevent* was restricted to those situations in which the boat had an initial tendency for the target (3). Likewise, participants did not choose *cause* or *enable* when the boat simply hit the cone (7), but only when the vector configurations matched those defined by the model. Thus, the Vector Model is capable of not only specifying distinct types of causal concepts, but also distinguishing between causation and non-causation.

The results strongly support the Vector Model, but only in the case of interactions occurring within a single dimension. In Experiment 2 we examine the ability of the model to handle two-dimensional interactions.

Experiment 2

Method

Participants. The participants were 18 University of Memphis undergraduates.

Materials. Ten 3D animations were made in the same way as in Experiment 1 except that the affector and patient force vectors were oriented in several directions other than directly towards or away from the target, and the magnitudes of the affector and patient vectors were always the same. The ten vector combinations at the top of Table 5 depict five combinations in which the patient vector is oriented away from the target by 45° (1-5) and five combinations in which the patient vector is oriented towards the target (6-10). The affector vector was oriented from 180° to 360° at 45° intervals.

Procedure The procedure was as in Experiment 1.

Results

The predictions of the Vector Model were supported once again. The bottom of Table 5 shows the percentage of times people chose each of the four possible options for each of the vector configurations. Participants chose *cause* for the animation in which the

boat was not headed for the cone but hit it because of the fans (2, a N-N-Y occurrence), $\chi^2(3, N=18) = 53, p < .001$. Participants chose *help* when the boat was headed for the cone and then was assisted in hitting it by the fans (6, a Y-Y-Y occurrence), $\chi^2(3, N=18) = 44, p < .001$. Participants chose *prevent* when the boat was initially headed toward the cone but was later blown away from it (7, 8, 9, 10, a Y-N-N occurrence), $\chi^2(3, N=18) = 229, p < .001$. Finally, participants chose "none of the above" when the vector configurations did not map onto any one of the three main kinds of configurations (1, 3, 4, 5), $\chi^2(3, N=18) = 238, p < .001$.

Conclusions

In this research we proposed a new model of causal meaning. We also provided empirical support for this model by showing that people's linguistic descriptions of animations are well accounted for by the model and its computer implementation given the same force vectors as those used to produce the animations.

According to the Vector Model, each kind of causal relation is associated with a range of spatial geometries in addition to a particular temporal organization. As a consequence, the model is able to handle causal relations that are highly problematic for probabilistic models, in particular, those in which the cause and effect occur simultaneously (*The sun's gravity causes the earth to revolve around the it*). In such situations, it is difficult to count the causing and resulting events for the purposes of calculating probabilities. In contrast, for the Vector Model, such situations are not problematic since they give rise to readily identifiable vector configurations.

The model provides a new explanation for why billiard-ball events, like the ones studied by Michotte (1963), are construed as causal. Traditionally, this was explained in terms of the spatial-temporal contiguity of the causing and resulting events. Clearly, spatial-temporal contiguity is important: without it, there can be no interaction of (contact-type) forces. But spatial-temporal contiguity is not particular to causal interactions alone. According to the Vector Model, what leads people to describe billiard-ball events as causal is that the patient resists moving (Tendency=N), the affector opposes this tendency (Concordance=N), and the patient ends up moving (Result=Y).

In sum, the Vector Model is able to address several important problems in the causation literature in addition to the two problems discussed in the introduction: the distinction between CAUSE and ENABLE and the expression of singular causation. It also takes us a step closer towards understanding how physical interactions may be construed for the purposes of language.

Abstract

Despite growing interests in the acquisition of Chinese orthography, few studies have modeled the acquisition process using connectionist networks. This study uses a self-organizing connectionist model to simulate children's learning of Chinese characters. There are two major goals of our study: (1) To evaluate the degree to which connectionist models can inform us of the complex structural and processing properties of the Chinese orthography. One of the most difficult tasks in achieving this goal is how to faithfully capture the orthographic similarities of Chinese characters. We derived our character representations on the basis of analyzing a large-scale character database that can be readily mapped to school children's orthographic acquisition. (2) To test the utility of self-organizing neural networks in orthographic acquisition. Most previous connectionist models of orthographic processing have relied on the use of feed-forward networks. Results from our simulations present positive evidence for both of our goals. In particular, we show that our model demonstrates early regularity effects and frequency effects in the acquisition of Chinese characters, matching up with acquisition patterns from empirical research.

Introduction

In recent years there have been growing interests in the psycholinguistic study of orthographic acquisition in Chinese (see Yang & Peng, 1997; Shu & Anderson, 1998; Shu, Anderson, & Wu, 2000). A unique feature of the Chinese orthography is that it uses characters rather than alphabetic letters as the basic writing unit, in square configurations that map mostly onto meaningful morphemes rather than spoken phonemes. Processing or acquisition within this "fractal" organization of characters may differ in important ways from that of English and other alphabetic languages (Shu & Anderson, 1998). There are four major types of Chinese characters: pictographic, referential, associative compounds, and ideophonic compounds. The last type, also known as

the semantic-phonetic compounds or, simply, phonetic compounds, is the most interesting and important. In the *Dictionary of Modern Chinese Frequent Characters* (National Language Commission, 1988), there are 5,631 ideophonic characters, accounting for 81% of the total 7,000 frequent characters in the dictionary (Li & Kang, 1993). Shu, Chen, Anderson, Wu, and Xuan (in press) collected 2,570 characters listed in the Elementary School Textbooks used in Beijing to establish the "School Chinese Corpus". They categorized and labeled every character in this corpus, on dimensions such as phonetic part, phonetic type, position of the phonetic part in the character, age at which the character is taught, and frequency of the character. Shu et al.'s analyses reveal that most of the Chinese characters taught in elementary schools are ideophonics, as shown in Table 1.

Table 1 Ratios of ideophonics in each grade
(Shu, Chen, Anderson, Wu, & Xuan, in press)

Grade	1	2	3	4	5	6	Mean
Ratio	.45	.70	.76	.84	.86	.81	.74

Given the prominence of ideophonics in Chinese orthography, it is thus important for us to understand the functions of these characters. Ideophonics consist of two major components: the semantic part (often called a radical) that gives information about the character's meaning, and the phonetic part that gives partial information about the whole character's pronunciation. We say "partial", because the phonetic radical may or may not indicate the true pronunciation of the whole character, in one of three ways: (a) Regular: the whole character is pronounced the same as the phonetic radical in isolation – that is, the same as the phonetic radical when it is being used as a simple character; for example, "清/qing1/" and "青/qing1/". (b) Semi-regular: the whole character is pronounced partly as the phonetic radical, with a different

tone (e.g., “请/qing3/ and “青/qing1/”), a different onset (e.g., “晴/jing1/ and “青/qing1/”), or a different final (e.g., “沙/sha1/ and “少/shao3/”). (c) Irregular: the whole character is pronounced completely differently from the phonetic radical (e.g., “猜/cai1/ and “青/qing1/”). These patterns of (ir)regularities in the pronunciations of ideophonetics influence the recognition and processing of Chinese characters, a phenomenon known as the *regularity effect* in the literature.

Previous studies have examined regularity effects in children's acquisition of Chinese characters. Shu, Anderson, and Wu (2000) showed that children display regularity effects when they are required to write down the pronunciations of Chinese characters: they perform better on regular characters (type a discussed above) than on irregular characters (types b and c). When children see unfamiliar characters, they often exploit the pronunciation of the phonetic radical as a possible reading of the whole character, and this ability increases with school grade. Yang and Peng (1997) also found regularity effects in children's speed of naming characters: children in Grade 3 name regular characters more rapidly than irregular characters, but by Grade 6, they name both types of characters equally quickly. Frequency also plays an important role in interacting with the regularity of characters; for example, Shu and Wu (1996) showed that children in Grade 3 display no regularity effects on characters of low frequency, while children in Grades 4 and 6 do. Finally, Shu, Zhou and Wu (2000) found that young children develop from early on phonological awareness of the structures of characters and the functions of the phonetic and semantic radicals. Some 4th graders already start to acquire the awareness of the consistency of phonetic radicals, and by Grade 6 this awareness becomes more transparent.

The above-mentioned properties of Chinese characters and the acquisition profiles therein lend themselves naturally to connectionist modeling. Given the discrepancy between regular and irregular characters, do we need to assume dual mechanisms to handle the two types of characters in acquisition (as symbolic theorists would like to argue)? Or rather, can we assume a connectionist learning mechanism that can capture the acquisition of both types of characters? Previous research in English has examined these issues in language acquisition and orthographic processing (e.g., Plaut, McClelland, Seidenberg, & Patterson, 1996; Seidenberg & McClelland, 1989). However, due to the difficulty in representing the complex structure of the Chinese orthography, there has been very little research in this domain in Chinese. In this study, we make an initial attempt to model the acquisition of Chinese orthography, in particular, the regularity effect in acquisition (as reported in empirical studies) with a neural network.

Method

Architecture

Most previous connectionist models of orthographic processing have relied on the use of feed-forward networks, typically with the back-propagation learning algorithm (e.g., Seidenberg & McClelland, 1989). Recently, a number of studies have explored self-organizing neural networks as viable models of language processing and language acquisition (Anderson, 1999; Miikkulainen, 1993, 1997; Li, 1999, 2000). Self-organizing networks are particularly well suited for the study of language acquisition, due to their biological plausibility, unsupervised learning, and the ability to develop semantic structures (Li, 2002).

In this study, we use a self-organizing feature map model developed by Miikkulainen (1997), originally for modeling disordered lexicons (DISLEX). DISLEX relies on principles of self-organization and Hebbian learning. In this model, different feature maps dedicated to different types of linguistic information (orthography, phonology, or semantics) are connected through associative links via Hebbian learning. To model orthographic processing, an input pattern activates a group of units on the orthographic input map, and the resulting bubble of activity propagates through the associative links and causes an activity bubble to form in the other map (semantic or phonological). Fig. 1 presents a diagrammatic sketch of the model's reading process from seeing the orthographic representation of *dog* to the comprehension of the word's meaning.

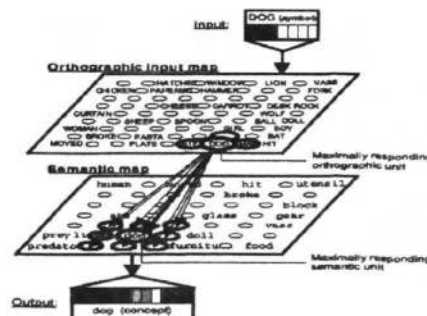

Fig.1 Reading comprehension of *dog* in DISLEX
(Miikkulainen, 1997; reproduced with author's permission)

If the direction of the associative propagation is from orthography to semantics, comprehension is modeled, as shown in Fig. 1; production is modeled if it goes from semantics to orthography. In our simulations, we examine the associative propagation from orthography to phonology to model the character naming process in the acquisition of ideophonetics by Chinese-speaking children. At this stage our model has not yet included semantic information.

Input Representation

There are a few general properties of Chinese characters that are important for us to consider for their accurate representations. (1) They are structurally complex.

The basic units of characters are strokes and components. A few simple strokes can make up a component, or a character; (2) They are combinatorially complex. Compound characters have two to over ten components, and these components combine to form a character according different rules in a hierarchically organized structure; (3) The majority of Chinese characters are ideophonic compounds, as discussed in *Introduction*; and (4) One character corresponds to one monosyllable in spoken language.

Phonological Representation. According to traditions in Chinese linguistics, the monosyllable of each character consists of three parts: initial, final, and tone (see Table 2). Initial is usually a consonant. Final consists of at least the nucleus vowel, sometimes with or without a head vowel or a tail vowel. The nucleus vowel may be one single phoneme or a diphthong (two phonemes). Lexical tones are supra-segmental, imposed on the initial and the final. In our representation scheme, we represent each phoneme (consonant or vowel) by 5 dimensions or features, and each feature by the phoneme's articulatory properties on a continuous scale from 0 to 1 (Table 3). The overall method of representation is similar to PatPho, a phonological representation scheme for English described by Li and MacWhinney (2002).

Table 2 Structure of the syllable and representation

Initial	Final			Tone
	Head Vowel	Nucleus Vowel	Tail Vowel	
5 dim.	5 dim	5 +5dms	5 dim	5 dim.

With this method we can represent all Chinese monosyllables with tone (a total of 1,335), each of which on a 30-dimensional feature vector. Table 3 lists the articulatory features we used to represent the Chinese phonemes.

Table 3 Articulatory features on 5 dimensions (D1-D5) for the representation of Chinese phonemes*

	vowel	voiced	voiceless				
D1	0.1	0.75	1.0				
D2	bilabial	Labio-dental	front	central	back	palatal	velar
	0.143	0.286	0.429	0.572	0.715	0.858	1.0
D3	round	nasal	stop	fricative	affricate	retroflex	lateral
	0.143	0.286	0.429	0.572	0.715	0.858	1.0
D4	high	mid	low				
	0.333	0.666	1.0				
D5	front	central	central-back	back			
	0.25	0.5	0.75	1.0			

* Numbers indicate dimensional values for each feature

Orthographic Representation. To accurately represent Chinese orthography in feature vectors has

proven a very challenging task, and this may have been the primary reason for the lack of modeling research in this domain, as we pointed out earlier. The only large-scale attempt in this respect was Chen & Peng (1994). They used 30 feature units to represent the various components of about 1,108 Chinese characters. Their representation scheme, however, is still insufficient for our purposes of modeling children's development in character acquisition. To overcome this bottleneck problem, we did a detailed analysis of all the characters in the *UCS Chinese Character Database* (Standards Press, 1994) and examined the strokes, components, and structures of these characters.

The *UCS Chinese Character Database* contains information about the structure and components for each of the 20,902 Chinese characters used in China, Japan, and Korea. This information includes the hierarchically ordered sequences of each component when characters are decomposed into smaller units of strokes. Other information includes pronunciation of the character, first-level categorization of the character, number of components, number of strokes, and frequency of usage. The database lists 560 basic components for the 20,902 Chinese characters, including the character's structural features, shape features, position of components, number of component strokes, etc. Most relevant for our study is the information about phonetic radicals in ideophonic characters. This includes the position of the phonetic radical in the character, whether the position of the radical is fixed, and the relationship between the pronunciation of the phonetic radical and that of the character. Finally, the database contains information about the frequency of each character in elementary school texts, as well as some of the original texts.

On the basis of our analyses of this database, we represented each ideophonic Chinese character with a 60-unit feature vector, along the dimensions as depicted in Fig.2.

Fig. 2 Orthographic representation of characters

The first 6 units represent the sound of the character, while the second 6 units represent the sound of the phonetic radicals. The purpose of these phonological units is to see how much overlap there is between the

pronunciation of the phonetic radical and that of the whole character. The next 48 units are used to represent component features, shapes, stroke structures, position of radicals, and stroke numbers. For example, component features include single, separate, crossing, and connecting; position of radicals includes top, bottom, left-side, right-side, middle, and inner, etc. The last unit is used for stroke numbers, and to determine the value of this unit, we analyzed the number of strokes of characters in our database. Given that most of the characters are between 1 to 10 strokes, characters with 10 or more strokes are represented as 1.0, and the rest as values (in decrements of .1) corresponding to the number of strokes (i.e., 0.9 for characters with 9 strokes, 0.8 for characters with 8 strokes, and so on).

Materials and Procedure

Materials. The basic training materials consist of groups or families of Chinese characters – characters in the same family have the same phonetic radicals, sometimes including the radical itself as a character. Because we are modeling elementary school children's acquisition of characters, the amount of character families differ for different grades, and the same family may also contain different numbers of family members, according to our analysis of the School Chinese Corpus (Shu et al., in press). We selected families of characters from the elementary textbooks for Grades 1, 3, and 5 as the basic materials in our training. Characters are selected as our input materials (a) if they have been learned in or before this grade, or (b) if the family includes all ideophonic characters that have been learned before. Table 4 shows the composition of our training materials, based on depth of learning in school grades.

Table 4 Selected characters and family compositions

Grade	Total characters	# of families	Mean members of a family
One	306	214	2.35
Three	305	139	4.33
Five	300	113	5.64

Training. Each batch of characters corresponding to each grade was submitted to the model, trained for 350 epochs for the self-organization of phonological representations and of orthographic representations. Upon training of the network, a phonological representation of a character was inputted to the network, and simultaneously, the orthographic representation of the same character was also presented to the network. By way of self-organization, the network formed an activity on the phonological map in response to the phonological input, and an activity on the orthographic map in response to the orthographic input. The phonological

representation of the character was also co-activated with its orthographic representation. As the network received input and continued to self-organize on each map, it simultaneously learned associative connections between maps through Hebbian learning: initially, all units on the phonological map were fully connected to all units on the orthographic map; as learning continued, only the units that were co-activated in response to the inputs were associated. As the end of learning, the network should have created compressed new representations in the corresponding maps for all the inputs and linked the phonological representation to its orthographic pattern. All simulations were conducted with the DISLEX simulator (Miikkulainen, 1999).

Testing. Once the network has completed self-organizing on the phonological and orthographic inputs and has learned the associative connections, we tested the model's performance by presenting the network with 16 ideophonic characters. We inputted the orthographic and phonological patterns of these 16 characters to the trained and well-settled network to test the output pronunciations of the characters in the model (see Fig. 1). No learning takes place at this stage. For each grade, a total of 48 characters was tested in the model, in three batches: 16 high frequency characters, 16 low frequency characters, and 16 new characters that have not been learned by the grade being tested.

Results and Discussion

Table 5 shows the overall performance of the network after it was trained for 350 epochs on all characters corresponding to each of the three grades being considered. These results show that the network achieved an average of 76% accuracy for orthographic representations; for phonological representations, it reached an average of 79% accuracy, and for the associative connections from orthography to phonology it achieved an average of 93% accuracy, a highly successful naming ability.

Table 5 Percent accuracy on orthography, phonology, and associative connections in the model after training

Grade	Ortho. map	Phono. map	Associative ortho.->phono.
One	75.6	78.4	90.5
Three	71.7	76.2	93.7
Five	80.2	82	95

Thus, after training, the model developed clearly structured representations for both the phonological and orthographic input patterns. Fig. 3 shows an example from the orthographic map trained on Grade 5 characters (only a portion of the entire map is shown here due to space limit).

Fig. 3 Orthographic map trained on Grade 5 characters

In Fig. 3, it can be seen that clear families of characters emerged in the map after the network was trained for 300 epochs on the Grade 5 characters. For example, one group of characters on the lower right-hand corner represents the “扁/bian3” family with “骗/pian4”, “编/bian1”, “偏/pian1”, “编/bian1”, “翩/pian”, while the other group on the upper right hand of the map represents the “合/he2” family with “盒/he2”, “鸽/ge1”, etc.

To see the model's ability in character naming, we tested the accuracy of its naming of regular and irregular characters for Grades 1, 3, and 5, with regular character being one that has exactly same pronunciation as its phonetic radical (see Introduction). The ratios of naming accuracy are presented in Fig. 4, on which we can make several observations: (a) the model's naming accuracy increases over time for both regular and irregular characters; (b) the difference in naming accuracy between regular and irregular characters also increases across grade; and (c) regularity effect does not exist for Grade 1 but becomes transparent for Grades 3 and 5. These results match up well with the empirical patterns observed by Shu et al (2000).

Fig. 4 Naming accuracy for regular and irregular characters

Interestingly, the regularity effect shown in Fig. 4 is modulated by character frequency. Ample empirical evidence suggests that frequency effect interacts with regularity effect in character acquisition (Shu, Anderson, & Wu, 2000). Table 6 shows that regularity effect in the model is only marginal for high frequency characters, but is much clearer for low frequency characters and novel characters (whose frequency is unknown to the network).

Finally, we analyzed the network's error types in naming irregular characters. In naming ideophonic characters, children as well as our network could use a

Table 6 Interaction between regularity and frequency

Frequency	Regular	Irregular
	.88	.83
Low frequency	.75	.46
New characters	.33	.17

variety of methods to get at the pronunciation of the irregular character. These methods allow us to discern regularity effects in reading acquisition. There are basically three major methods they could use: (1) reading the irregular character as the pronunciation of its phonetic radical (e.g., “橙/cheng2” as “登/deng1”); (2) reading the character as another character having a similar orthography/radical in the same family (e.g., “编/bian1” as “偏/pian1”); and (3) reading the character as other irrelevant characters (e.g., “纵/zong1” as “凯/kai3”). Table 7 shows the ratio of the network's erroneous naming of irregular characters for each grade, as a function of naming methods (M1 = Method (1); M2 = Method (2); and M3 = Method (3)).

Table 7 Network's naming for irregular characters

Grade	Irregular Character Naming Errors		
	M1	M2	M3
One	.06	.25	.69
Three	.36	.46	.18
Five	.30	.50	.20

Table 7 shows several interesting patterns. First, for Grade 1 the network's errors are mainly based on Method 3, i.e., reading characters as irrelevant characters. This shows that regularity effect has not played much of a role yet in the naming of irregular characters. For Grades 3 and 5, however, the error types shift more toward Methods 1 and 2, showing that the model is exploring orthographic and phonological similarities of the radical to give possible pronunciations of the irregular character. These developmental patterns of regularity effect are consistent with empirical data from Shu et al (2000), according to which children, although in principle can utilize ideophonic information early on, show regularity effect only after they have learned a relatively large number of items in the ideophonic families.

Conclusion

This study uses a self-organizing connectionist model to simulate children's acquisition of Chinese characters. There are two major goals of our study. First, we wanted to see if connectionist models can be applied successfully to model the learning process in the acquisition of Chinese characters, a topic that has not been touched on in the literature. Given the complex structural and processing properties of the Chinese orthography, it is only natural that we examine this

domain with systematically varying modeling parameters. One of the most difficult tasks in achieving this goal is how to faithfully capture the orthographic similarities of Chinese characters, as discussed in *Method*. We derived our character representations on the basis of analyses of a large-scale character database that can be readily mapped to school children's orthographic development.

The second goal of our study is to test the utility of self-organizing neural networks. Most previous connectionist models in this domain have relied on the use of feed-forward networks, typically with the back-propagation learning algorithm. In previous research, Miikkulainen (1993, 1997) explored self-organizing neural networks as plausible models of language and memory processing, and Li (1999, 2000, 2002) showed these networks as viable models of language acquisition. We wanted to see if such models can be used successfully to examine orthographic acquisition. Our initial simulations as presented here seem to provide positive evidence in this respect. In particular, we showed that our self-organizing network demonstrates regularity effect and frequency effect in the acquisition of Chinese characters, and that these results match up with developmental patterns observed in empirical research. In future studies, we will continue these lines of experiments to examine frequency effect, phonological consistency effect, and their interaction with regularity effect in character acquisition, addressing other relevant theoretical issues in connectionist language acquisition.

Acknowledgments

This research was supported by a grant from Natural Science Foundation of China #60083005 to H.S., and in part by an NSF grant #9975249 to P.L. while the first author was visiting the Cognitive Science Lab at the University of Richmond. We would like to thank Risto Miikkulainen for making available the source code of the DISLEX program, and Igor Farkas for helping with the set-up of the simulations.

Abstract

We report 4 studies which show that there are systematic quantitative patterns in the way we reason with uncertainty during causal and counterfactual inference. Two specific type of uncertainty – uncertainty about facts and about causal relations – are explored, and used to model people's causal inferences (Studies 1-3). We then consider the relationship between causal and counterfactual reasoning, and propose that counterfactual inference can be regarded as a form of causal inference in which factual uncertainty is eradicated. On this basis we present evidence that there are also systematic quantitative patterns underlying counterfactual, as well as causal, inference (Study 4). We conclude by considering the consequences of these results for future research into causal inference.

Introduction

The ability to make causal inferences is of central importance to cognitive agents wishing to control or predict events in the world. However, many of our beliefs are held with less than perfect certainty. Given this, it is natural to enquire about the way in which uncertainty affects the process of reasoning about the world. In this paper we examine the way in which two types of uncertainty – uncertainty about facts and uncertainty about causal relations – are assimilated during the process of causal and counterfactual inference. Studies 1-3 reveal that there are systematic quantitative patterns in our treatment of uncertainty in causal inference, suggesting that our understanding of causality is not inherently deterministic as has recently been proposed (Goldvarg & Johnson-Laird, 2001). We then consider the relationship between causal and counterfactual inference, and show that modified forms of the models which can be used to predict causal inference can be used to predict counterfactual inference (Study 4), a result consistent with theories which treat counterfactuals as supervenient on causal knowledge (Pearl, 2000; Yarlett & Ramscar, in press; Jackson, 1977). We conclude by considering the consequences of these results for future research into causal and counterfactual inference.

Causal Inference and Uncertainty

We make a causal inference when we acquire some new evidence about a cause, and on this basis update our beliefs about effects related to that cause. For example, imagine you meet Tom at a party. During your brief conversation, he says and does certain things that make you think he is an Army Officer, although you're not completely certain about this. As a result of this suspicion you might now think it more likely that Tom is able to fire a pistol and abseil, compared to when you first met him. Your beliefs about Tom have changed as a result of causal inference.

When it comes to making causal inferences, two types of uncertainty are especially important: *factual uncertainty* and *causal uncertainty*. Factual uncertainty arises simply because our experience of the world is in many cases insufficient to allow us to be completely certain about our beliefs. For example, Tom's extensive knowledge of firearms and military strategy, as displayed in your conversation, might make you suspect that he is in the Army. But you are nevertheless aware that you could be wrong about this. Therefore there is some factual uncertainty in your belief that Tom is in the Army.

The second type of uncertainty relevant to making inferences about the world is *causal uncertainty*. This arises because although there are systematic regularities in the world, these rarely obtain without exception. For example, we all agree that clouds cause rain, even though rain does not invariably fall when it is cloudy; and we would probably also concur that smoking causes cancer, although we know that not all smokers contract cancer. Causal uncertainty, then, arises because of our awareness that although events of type A may tend to produce events of type B, it is not the case that As are *always* or *invariably* followed by Bs.

Although it seems intuitively plausible that both factual and causal uncertainty should play a role in determining our causal inferences, to our knowledge very little empirical work has explored this issue. Some previous work has found an effect of factual uncertainty in both deductive (Stevenson & Over, 1995; Byrne, 1989) and causal (Cummins *et al.*, 1991) settings, but

none of these studies examined the systematic effects of factual uncertainty from a quantitative perspective. And although it seems reasonable to assume that causal uncertainty plays a role in causal inference and reasoning – and indeed, many recently proposed theories (e.g., Cheng, 1997; Pearl, 2000) and models (Rehder, 1999; Yarlett & Ramscar, in press) concerned with causal reasoning successfully make this assumption – it is by no means uncontroversial. Goldvarg & Johnson-Laird (2001) have recently argued that the meaning of causal statements is inherently deterministic, and more generally, theories of reasoning which invoke mental models do not easily permit the accommodation of less than certain inferences (but see Johnson-Laird, 1994, and Stevenson & Over, 1995). The present series of studies therefore set out to investigate whether factual and causal uncertainty play a role in the process of causal inference and, if so, whether they do so in a systematic fashion.

Study 1

Study 1 was designed in order to get ratings about the causal uncertainty attaching to a specific set of cause-effect pairs, in order to explore the structure of the information with which people relate causes and effects, and also to investigate the information that might be used in causal inference. People were asked to rate the causal uncertainty attaching to a range of cause-effect pairs on a range of scales which measured: (i) how strongly the cause causes the effect; (ii) how strongly the effect depends on the cause; (iii) the conditional probability of the effect given the presence of the cause; and (iv) the conditional probability of the effect given the absence of the cause. In addition to the ratings collected, the following ratings were derived from the conditional probability ratings:

$$\Delta P \text{ Contingency} = P(e|c) - P(e|\sim c)$$

$$\text{Power PC} = \frac{P(e|c) - P(e|\sim c)}{1 - P(e|\sim c)}$$

These quantities have variously been proposed as measures of the strength of a cause (e.g. Cheng & Novick, 1992; Cheng, 1997).

Materials and Design. The materials used described 10 different cause-effect pairs. They were selected in order to cover a wide variety of domains, and included the following pairs: smoking and cancer; cars and pollution; stress and insomnia; sunbathing and suntanning; weight-training and muscle-growth; cholesterol and heart attacks.

Subjects were asked directly about the strength of relation that they thought held between the pairs in question. For example, for the smoking-cancer pair, the

	Factor 1 (Causal Power)	Factor 2 (Base rate)
Causal	0.969	-0.042
P(e c)	0.927	-0.326
Power PC	0.873	-0.481
Dependency	0.699	-0.600
ΔP	0.664	-0.738
P(e ~c)	-0.106	0.982

Table 1: Factor loadings from Study 1.

following questions were used: (i) "How strongly do you think smoking causes cancer?"; (ii) "How strongly do you think whether someone gets cancer depends on whether they smoke?"; (iii) "How likely do you think someone would be to get cancer given that they smoke?"; and (iv) "How likely do you think someone would be to get cancer given that they do not smoke?" All ratings were collected on a 0-100 scale. For the causal ratings the scale was anchored by 'does not cause at all' and 'always causes'; for the dependency ratings 'does not depend at all' and 'perfectly depends'; and for the subjective probability ratings 'completely unlikely' and 'completely certain'.

Three groups were asked to rate the causal, dependency, and conditional probability ratings. A within-subjects design was not used because of concerns that this would artificially homogenise what might in reality be different ratings (e.g. being asked to rate causal, dependency and conditional probability ratings consecutively might encourage subjects to simply return similar ratings on all scales).

Participants. 49 students from the University of Edinburgh participated voluntarily.

Results. A factor analysis (principal-components analysis with rotated axes) was conducted on the ratings in order to examine their structure. Only the first two rotated factors had eigenvalues greater than 1, and these together accounted for 95.16% of the variance in the data. The factor loadings are shown in Table 1.

Discussion

The two factors extracted in the factor analysis successfully explained a large proportion of the variance in the causal uncertainty ratings collected in Study 1. Moreover, the extracted factors are readily interpretable because the causal ratings load very highly on the first factor (0.969) and negligibly on the second factor (-0.042), while the P(e|c) ratings load very highly on the second factor (0.982) and negligibly on the first factor (-0.106). Study 1 therefore suggests that two factors are especially important in accounting for our representation of causal uncertainty: the causal strength with which a cause produces its effect ('Causal Power'), and the base rate of the effect in the absence of the cause ('Base rate'). This suggests that models of

Model	Definition
Probabilistic	$P(e c)P(c) + P(e \sim c)P(\sim c)$
Linear	$P(e \sim c) + \text{causes}(c,e)P(c)$
Noisy-OR	$1 - [1 - P(e \sim c)][1 - \text{causes}(c,e)P(c)]$
Causal	$\text{causes}(c,e)P(c)$
Dependency	$\text{depends}(e,c)P(c)$

Table 2: The models of causal inference.

causal inference should incorporate these two parameters. This proposal was investigated in Study 2.

Study 2

Study 2 examined the degree to which causal inference can be modelled using information about factual and causal uncertainty. The ratings from Study 1 were used in order to provide information about the degree of causal uncertainty attaching to the 10 causal pairs, while new data was acquired concerning their factual uncertainty. Short scenarios centring around each of the 10 causal pairs were designed, in which it was deliberately made unclear whether the cause was present or absent. These were used to induce factual uncertainty in participants in the study. For example, the scenario for the smoking-cancer causal pair ran as follows:

"Imagine you're introduced to Bill, a friend of a friend, one day. You ask Bill for a lighter but he doesn't carry one. However, it does look a little as though he might have tobacco stains under his nails."

After reading each description, participants were requested to rate their factual uncertainty, on a 0-100 scale, by being asked how likely they thought it was that the cause was present given what they had read (i.e., in this case how likely they thought it was that Bill was a smoker). They were then asked to make a causal inference by judging, given their confidence that Bill may or may not be a smoker, how likely they thought he would be to contract cancer at some point in his life. The information collected about factual and causal uncertainty was then used to parameterise various models of causal inference, in order to see if the inferences participants made could be predicted.

Models of Causal Inference

The models of causal inference investigated are listed in Table 2. The probabilistic model defines the normative method of inferring the probability of an effect given information about a related cause. The linear model, in contrast, states that one's belief in an effect is the combination of a base rate of belief – the belief that the effect is present in the absence of the cause – plus the extra support that the cause provides for belief in the

effect, which is defined as the product of one's belief that the cause is present and the degree to which the cause and effect are causally related. The noisy-OR model (Pearl, 1988) treats causes as mechanisms that operate independently and additively to produce a common effect. The probability of an effect in this framework is thus given as the probability that not all the causes fail to generate the effect.¹ Finally, the causal model predicts that people's belief in the cause is a product of the degree to which the cause and effect are causally related, and the degree to which the cause is believed to be present. And the dependency model is similar to the causal model, except that it measures causal uncertainty using dependency, instead of causal strength, ratings.

Materials and Design. The cause-effect pairs and connection ratings from Study 1 were used. In addition, scenarios for each causal pair were designed in order to embed the causal relation in a specific context, and deliberately induce factual uncertainty as to whether the cause in question was present or not.

A within-subjects design was deliberately eschewed in Study 2 because of concerns that it could artificially bring people's causal inferences in line with the predictions of the probabilistic model. Many people are familiar with basic probability theory, and our concern was that being asked to rate the conditional probability of the effect given the cause before making their causal inference (as a within-subjects design would have required), could force people to reason about the effect arithmetically, in opposition to their natural style of reasoning. Accordingly, a between-subjects design was adopted, in which the causal uncertainty ratings used were those collected in Study 1, while the factual uncertainty ratings and the causal inferences themselves, were collected in the present study.

Participants. Participants were 21 students at the University of Edinburgh. All participants were volunteers, and no reward was offered for participation.

Results. The performance of the models of causal inference is shown in Figure 1. The probabilistic ($r = 0.665$, $p < 0.05$, one-tailed), linear ($r = 0.621$, $p < 0.05$, one-tailed), and noisy-OR ($r = 0.711$, $p < 0.05$, one-tailed) models were all significant predictors of people's causal inferences. The causal ($r = 0.495$, $p > 0.05$, one-tailed) and dependency ($r = 0.268$, $p > 0.05$, one-tailed) models, however, failed to significantly predict people's inferences. A further analysis was also

¹ Interestingly, the linear and the Noisy-OR models of causal inference find their counterparts in the ΔP and Power PC theories of causal induction respectively (they can be derived as the maximum likelihood estimates of causal strength parameters in causal graphs appropriately parameterised; see Glymour, 1998; Tenenbaum & Griffiths, 2000).

Figure 1: Results of Study 2.

conducted on the linear and noisy-OR models, because they could also be parameterised with conditional probability instead of causal strength ratings. In both cases, parameterising the models with the conditional probability of the effect given the presence of the cause, instead of the causal strength ratings, served to increase their empirical performance (see Figure 2).

Discussion

The fact that the linear, noisy-OR and probabilistic models were significantly correlated with the strength of people's causal inferences suggests that information about factual and causal uncertainty plays an important role in the inference process, and also that there seem to be domain-general quantitative patterns in the way we reason from cause to effect. However, the factual and causal uncertainty ratings and inferences predicted in Study 2 were between-subjects aggregates. It is therefore possible that the success of the proposed models is merely an artefact of the experimental design, and that the models would prove unable to predict causal inferences on a within-subjects basis. Study 3 investigated this issue, while also allowing us to examine how much of the residual error in the causal models could be attributed to idiosyncratic use of the rating scales.²

Study 3

Study 3 used a within-subjects design in which people estimated the factual and causal uncertainty attaching to each of the 10 cause-effect pairs, and then made a causal inference about the effect. Because the causal and dependency models failed to significantly predict people's inferences they were dropped from

² Because Study 2 had shown that the probabilistic model predicted causal inference with some level of success in a context in which patterns of causal inference consistent with the predictions of the probabilistic model could not have been artificially induced, the use of a within-subjects design was now appropriate.

Figure 2: Effect of changing parameterisation of Linear and Noisy-OR models.

consideration. Instead we focused on the performance of just the probabilistic, linear and noisy-OR models.

Materials and Design. The causal pairs and materials as used in Studies 1 and 2 were again used in this study. Each subject saw all 10 scenarios, in one of two reverse-orderings. The linear and noisy-OR models were parameterised using only conditional probability, and not causal strength ratings, because of the better performance of this form of the models in Study 2.

Participants. Participants were 15 students enrolled at the Division of Informatics, University of Edinburgh. All participants were volunteers, and no reward was offered for participation.

Results. The performance of the causal models is shown in Figure 3. Both the linear ($t = 2.280$, $df = 14$, $p = 0.038$, two-tailed) and the noisy-OR model ($t = 2.379$, $df = 14$, $p = 0.032$, two-tailed) performed significantly better than the probabilistic model, although there was no significant difference between the linear and noisy-OR model ($t = 1.302$, $df = 14$, $p = 0.214$, two-tailed). The degree of variance explained in the inference process by just taking into account either the amount of factual uncertainty, in the form of the $p(c)$ ratings, or the amount of causal uncertainty, in the form of the $p(e|c)$ ratings, is also shown in Figure 3 for comparison. These two models performed significantly worse than all the other models.

To confirm that both the factual and causal uncertainty parameters added to the models' predictive validity the performance of the linear and noisy-OR models was compared to modified versions of them in which (i) factual uncertainty was ignored; and (ii) causal uncertainty was ignored. The linear model performed significantly better than its counterpart which ignored factual uncertainty ($t = 2.358$, $df = 14$, $p = 0.017$, one-tailed), and marginally better than its counterpart which ignored causal uncertainty ($t = 1.546$, $df = 14$, $p = 0.072$, one-tailed). The noisy-OR model performed significantly better than both its modified

Figure 3: Results from Study 3.

versions which ignored factual ($t = 4.199$, $df = 14$, $p < 0.001$, one-tailed) and causal ($t = 2.049$, $df = 14$, $p = 0.030$, one-tailed) uncertainty.

Discussion

The results of Study 3 show that quantitative models – particularly the linear and noisy-OR model – can successfully predict people's causal inferences with some degree of success. Moreover, the results of Study 3 also show that removing information about either factual or causal uncertainty from these models significantly decreases their performance, thus showing that these factors do seem to play an important role in causal inference.

Causes and Counterfactuals

The studies reported so far examined the role of uncertainty in causal reasoning. However, there is an intimate connection between causal and counterfactual reasoning (c.f. Lewis, 1973b; Jackson, 1977; Pearl, 2000; Yarlett & Ramscar, 2001). In the light of this it is interesting to examine whether the findings concerning causality in Studies 1-3 can also be applied to counterfactual reasoning.

The proposal we examined is that, at least in the present context, counterfactual reasoning can be treated as a form of causal reasoning in which residual factual uncertainty is eliminated (for treatments of counterfactual reasoning in more complex systems see Yarlett & Ramscar, in press, and Pearl, 2000). For example, imagine that you are fairly sure that Bill is not a smoker, but that I ask you how likely you think he would be to contract cancer if (counterfactually) he were a smoker. Even though there may be some factual uncertainty in your belief that Bill is not *actually* a smoker, there should be no factual uncertainty attaching to the counterfactual scenario because the counterfactual asks you to assume, unequivocally, that he is a smoker. Study 4 investigated this proposal.

Figure 4: Results from Study 4.

Study 4

Study 4 investigated whether quantitative patterns could be found underlying counterfactual, as well as causal, inference. The scenarios used in Studies 2 and 3 were altered so that instead of engendering uncertainty they were perfectly unambiguous that the cause in question was absent. Then, instead of being asked to make a straightforward causal inference, subjects were asked to consider how strongly they would believe in the effect *if the cause were present*.

Materials and Design. The materials used were adapted forms of the scenarios used in Studies 2-3. Here is the smoking scenario, with the added information shown in *italics*:

"Imagine you're introduced to Bill, a friend of a friend, one day. You ask Bill for a lighter but he doesn't carry one. However, it does look a little as though he might have tobacco stains under his nails. It later turns out that Bill is not a smoker; in fact he's never even smoked a cigarette in his life."

Subjects were then asked to rate "But if Bill were a smoker, how likely do you think he would be to get cancer at some point in his life?". Data was collected using a between-subjects design, as used in Study 2.

Participants. Participants were 23 students at the University of Edinburgh.

Results. The results of Study 4 are shown in Figure 4. The causal model ($r = 0.699$, $df = 8$, $p < 0.05$, one-tailed), linear model parameterised with causal strength ratings ($r = 0.667$, $df = 8$, $p < 0.05$, one-tailed), and noisy-OR model parameterised with either conditional probabilities ($r = 0.589$, $df = 8$, $p < 0.05$, one-tailed) or causal strengths ($r = 0.571$, $df = 8$, $p < 0.05$, one-tailed), significantly predicted people's counterfactual inferences.

Discussion

The results of this study show that modified forms of the models used to predict causal inferences can also be employed in the prediction of counterfactual inferences, and also that counterfactual inference can be profitably regarded as a special case of causal inference in which factual uncertainty has been eradicated. This result is both consistent with theories which hold that counterfactuals supervene on causal relations (e.g., Jackson, 1977; Pearl, 2000; Yarlett & Ramscar, in press), and at tension with theories that treat counterfactual judgements as propositions assigned binary truth-values (e.g., Byrne, 1997; Byrne & Tasso, 1999; Lewis, 1973). However, given the success of multiple models at capturing the quantitative patterns in counterfactual inference exhibited in Study 4, clearly further work is required to tease the models apart, and determine whether patterns in both causal and counterfactual inference can be successfully captured by the same models.

General Discussion

The 4 studies reported here suggest that both factual and causal uncertainty play an important role in determining causal and counterfactual inference, and furthermore that counterfactual inference can profitably be regarded as a form of causal inference in which factual uncertainty is eradicated. However, one potential cause for concern is the often considerable amount of variance left unexplained by the sort of quantitative models described in this paper. Clearly more work needs to be done before the role of such models in describing causal and counterfactual inference is fully understood. In particular, in future work we intend to examine whether alternative ways of measuring causal and factual uncertainty can increase the explanatory power of the quantitative models, and also whether additional factors can be imported into the models to improve their empirical fit (e.g. how many alternative or preventative causes exist for a specific cause effect pair being reasoned about; see Cummins *et al.*, 1991).

Linguistic cues enhance the learning of perceptual cues

Hanako Yoshida (hayoshid@indiana.edu)

Abstract

Past research on children's categorizations has centered on the mechanism of children's use of multiple cues in categorization. This paper examines correlations between perceptual cues and linguistic cues. The question asked is a classic one in learning theory: given two redundant cues, does the learner learn more about each than when one cue independently predicts the category? This question has special cogency in the context of children's language learning. We show that when linguistic cues correlated with perceptual cues, children learn more about perceptual cues.

Introduction

Two- and 3-year-old children learn new object names rapidly, often correctly determining the range of instances to which the name applies from just one experience hearing the word used in a single context. Children do this by exploiting multiple cues to meaning. Past research indicates they use both linguistic cues and perceptual cues to figure out the likely meaning of a novel noun. Much of the relevant evidence in this literature concerns the count-mass distinction in English. Count nouns refer to entities conceptualized as discrete objects and as countable. Count nouns obligatorily take the plural (e.g., cups, hopes). Mass nouns refer to entities conceptualized as continuous substances and do not take the plural, but rather mass quantifiers (e.g., some water, a lot of sand). Children use linguistic cues to the count/mass status of a noun to figure out the category to which a novel noun refers. For example, if an entity named with a novel name is presented in a frame that indicates it is a count noun (e.g., "This is a mel"), English-speaking children interpret the word as referring to a discrete entity and typically extend the object name to a class of similarly shaped things (Soja, Carey & Spelke, 1991; Soja, 1992; Landau, Smith and Jones, 1988; Landau, Smith and Jones, 1998; Imai & Gentner, 1997). When the same noun is presented in a frame indicating it is a mass noun (e.g., "This is some mel"), English-speaking children interpret the word as referring to a substance and extend its meaning to entities of the same material (Soja, Carey & Spelke, 1991; Soja, 1992).

Children also use perceptual cues. For example, children extend novel names to new instances by shape when the named entity is solid and rigid (e.g., made from wood) but extend the name to new instances by material when the named entity is nonsolid and non-rigidly shaped. Much previous research has explored which of these kinds of cues dominate by putting them in conflict. In this paper, we ask whether and how they might interact and support children's learning of object names. This is a relevant question for two reasons.

First, linguistic and perceptual cues are highly correlated. This was documented by Samuelson and Smith (1999) who studied the structure of the first 300 nouns commonly learned by English-speaking children. Among these 300 names for common categories, solid things tend to be named by count nouns that refer to things of the same shape, whereas nonsolid things tend to be named by mass nouns that refer to entities of the same material. For learners of English, then, there is a tight correlation between linguistic cues associated with count/mass distinction and perceptual cues that indicates the solidity or non-solidity of an entity.

Second, the evidence suggests that children learn the correlations among perceptual cues, linguistic cues, and category structure as they learn names for common object and substance categories. Specifically, the influence of perceptual cues on children's noun extensions emerges and grows stronger as vocabulary grows. Samuelson and Smith's (1999) data indicate that children learning English do not extend names for solid and nonsolid things differently until children have over 150 nouns. Similarly, English-speaking children's sensitivity to count/mass syntax in the novel noun extension task emerges during this same time period (Soja, 1992).

Two hypotheses

What is the relation between learning about perceptual cues to category organization and linguistic cues to category organization? One possibility is that they are completely independent. Cross-linguistic comparisons of English and Japanese speakers are consistent with this view. Japanese differs from English in that it has no obligatory plural and no counterpart to the count-mass distinction in English. Yet, several studies suggest that

Japanese-speaking children extend names for novel solids and non-solids in pretty much the same way as English-speaking children (e.g., Imai & Gentner, 1997). Thus, children's learning about perceptual correlations and their learning about syntactic cues to category structure (so-called syntactic bootstrapping) may proceed from different learning mechanisms. At the very least, learning about perceptual correlations does not require support from linguistic correlations.

The second contrasting possibility is that learning about perceptual and linguistic cues to category structure are mutually reinforcing. Imai & Gentner's (1997) comparisons of Japanese-speaking and English-speaking children's extensions of names for novel solids and non-solids suggest some subtle differences in the range of items treated as objects and substances, and also some differences in the developmental trend (see, also Yoshida & Smith, 2001.) Further, a number of learning models (Billman & Knutson, 1996; Medin, Altom, Edelson and Freko, 1982; Goldstone, 1998) suggest that the addition of correlated cues bolsters learning about each cue.

Rationale for the experiment

In the present experiment, we examine the role of syntax in children's learning about perceptual cues to category structure through a training study. We attempted to train the solid-nonsolid distinction in Japanese-speaking children who were too young to robustly make the distinction in their novel noun extensions (Shirai, 2000). The design of the four training conditions is shown in Table 1. The linguistic cues are *hitotsu* and *sukoshi*. In the specification of quantitative constructions, (e.g., There is one cup) *hitotsu* is used with objects and *sukoshi* is used with substances. This is thus a natural and salient lexical contrast in Japanese, yet it is one that is neither mandatory nor particularly common. This is in contrast to the count-mass distinction in English, which is mandatory and pervasive. In control conditions, we show that Japanese-speaking children are not sensitive to this contrast, and do not know its implications concerning objects and substances, prior to training.

During the test phase, half of the children in each condition were tested with the linguistic cues and half were not. Here, then, is the question: Will Japanese speaking children show a stronger distinction in their novel noun generalizations between solids and non-solids if trained with these correlated linguistic cues than if trained without them? Is this so even when the linguistic cues are not present during testing? Because our design involves using natural and thus potentially meaningful lexical cues, and because we attempted to accelerate the emergence of a distinction that children eventually learn, we also included two control conditions. Neither involved any training but tested

children's sensitivity to the linguistic and perceptual cues.

Experiment

Method

Participants Forty monolingual 2-year-old Japanese-speaking children residing in Niigata, Japan, were randomly assigned to the two training conditions and one control condition. Half of the children in each condition participated in the novel noun generalization test at the end of training, either with linguistic cues or without linguistic cues in the tasks, for a total of 6 conditions.

Stimulus Training stimuli consisted of 4 training pairs, two solids and two non-solids, as shown Figure 1. The items in the solid pairs were the same shape but differed substantially in material and color. The items in each nonsolid pair were the same material but differed substantially in color and shape. Stimuli for the test trials consisted of novel solid items made of wood, clay, or sponge, and novel nonsolid items made of hair gel, hand cream, or toothpaste. During test, children were queried about 6 unique test sets, 3 times each for a total of 18 trials per a participant. Each of these test sets contained one exemplar and 3 choice objects unique to that set. One test choice object matched the exemplar in shape only, one matched in material only, and one matched in color only (See Figure 2.) During test, the exemplars were named with a novel name with and without the lexical cues *hitotsu* and *sukoshi* corresponding to the condition to which the participants were assigned.

Design and procedure Children participated in one of the 6 conditions that resulted from crossing the 3 levels of training (training with correlated linguistic cues, training without correlated linguistic cues, and absence of training), 2 levels of linguistic cues (with/without linguistic cues in the task) with 2 levels of solidity (solid/non-solid) for each condition.

Children in the Training condition participated in 10 training sessions over a period of 4 weeks. During each session, the child was presented with the training stimulus repeatedly with/without correlated linguistic cues depending on the child's condition. Each stimulus was shown and introduced by its own novel name, and then played with and repeatedly named for 5 minutes. Each training session took a place for approximately 30 minutes every other day. Notice, this is an implicit category-learning task. During training, children are not required to discriminate between category instances, but attend to the linguistic cues as predictive of category membership.

All children participated in the same test trials where the child was shown an exemplar of a test stimulus set

and told its unique novel name with and without corresponding linguistic cues; "This is (*hitotu/sukoshi*) kochi" or "This is (*hitotu/sukoshi*) kochi". The child was then presented with 3 test objects and was asked to hand the item that can be considered as the name of the exemplar with and without corresponding linguistic cues; "Where is (*hitotu/sukoshi*) kochi?" or "Where is kochi?" Feedback was not provided on these test trials. Since these are novel objects and novel names, success requires knowledge of some general principle---that solids are named by shape and nonsolids are named by material. Are children more likely to notice this regularity when there are correlated linguistic cues?

Results

Each graph in Figure 3 shows the percentage of children's "correct novel word generalization" for solid and non-solid items where "correct" was considered to be shape based for the solids and material based for the non-solids.

Two graphs in the top row represent the performance of children without training sessions. Children generalized all names the same---by shape---treating solids and non-solids equally. This shows that, prior to training, children are not sensitive to the linguistic distinction, nor given these stimuli, to the solid-nonsolid distinction. The two graphs in the bottom represent the performance of children participated in the training sessions with corresponding syntactic cues. The graph on the left shows children's performance without the corresponding syntactic cues in the test trials and one on the right shows children's performance with the corresponding syntactic cues.

Overall, children who had training sessions with the linguistic cues generalize novel names correctly more often than of children without the training sessions, $F(1, 28)=27.2$, $p<.01$. The results suggest that the presence of correlated linguistic cues enhances learning about perceptual cues;

Discussion

The training study revealed the importance of correlated cues in category learning by demonstrating how correlations between linguistic cues and perceptual cues mutually reinforce attention to relevant perceptual cues in the name extension task. The findings fit the traditional idea of how language influences thought.

Whorf. (1956, p.252) wrote

And every language is a vast pattern-system, different from others, in which are culturally ordained the forms and categories by which the

personality not only communicates, but also analyzes, notices or neglects types of relationship and phenomena....

If correlated linguistic cues influence what is learned about perceptual cues, Whorf will be right: the language one learns will influence what one notices or neglects to notice about the world.

Table

Abstract

People gesture when they speak. Despite considerable attention from a variety of disciplines, the precise nature of the relation between gesture, speech and thought has remained elusive. The research reported here considers two very different hypotheses about the fundamental relationship. By one account, gesture is a consequence of physiological arousal. By another account, gesture use reflects more cognitive processes and is strongly linked to mental representation. This paper seeks the mechanism underlying the link between gesture and speech by showing that both mental representation and physiological arousal are reflected in our gesture use.

Introduction

Communication is the activity of transmitting information about things in the world. In everyday life, we refer to things by employing a number of communicative tools. Language, gestures, facial expressions, and non-linguistic vocalizations are often considered communicative tools. Interestingly, we integrate multiple modalities in our communication and indeed, past research suggests a tight link between modalities, and particularly between speech and gesture.

This study is motivated by two approaches to the study of gesture. McNeill (1992), Kita (2000) and McNeill & Duncan (2000) consider the relationship between the specific forms of gesture and speech, specifically between iconic gesture and speech. An iconic gesture is one in which the speed, motion, or shape of the gesturing hand resembles the meaning being conveyed. McNeill and colleagues consider the emergence of iconicity in gesture as natural, and due to the embodied and imagistic nature of thought. Another approach, however, considers gesture as a consequence not of meaning, but of arousal. Schwartz & Black, (1996) and Iverson & Thelen (1999) particularly suggest that gestures can be explained as an overflow of one's excitement, which is physiologically produced by speech. The idea here is that speech is a motor program, and as the speaker is aroused—by topic or by the very act of speaking—that energy overflows and is evident in other bodily movements.

This present research is concerned with one flashpoint in these accounts: the idea that gesture use fluctuates. At present, the variability in gesture use and in kind of gesturers is not well explained. Yet this very variability should be the key to underlying mechanism. We demonstrate the bi-directional relationship between gesture, thoughts and arousal by confirming that both mental representation and arousal are reflected in and influence iconic gesture use. We experimentally manipulate speech rate as a means of increasing the "motor overflow" from speech. Although speech rate is at best an indirect marker of arousal, we believe it is a good starting point for a mechanistic explanation of variability in gesture use.

Iconicity

Communicative tools in general range from conventional forms that are more arbitrary, to less conventional forms that are more iconic. An example of the conventional forms in traditional verbal languages would be the word "dog" which can hold the meaning only when both senders and receivers are knowledgeable about the rule indicating the label—"a dog" means a dog. This form can also be seen in written language when one spells out letters, d, o, g to refer to a dog. Again, receivers can make sense out of the particular combination of letters only by knowing the convention, that the order and the combination of letters are signifying a dog. People also refer iconically. For example, in verbal language use, one might imitate a sound of a dog to refer to a dog (e.g., "woof, woof!"), and in American Sign Language the word for a dog consists of a pat on one's leg and a snap of one's fingers as if calling a dog.

People also often gesture iconically (Kita, 2000). For example, a speaker might make a circle with one's hands to describe shape and/or the size of a plate to which the person refers. Indeed, even nonverbal primates may gesture to convey meaning. For example, Tanner and Byrne (1996) recently reported that several observed gestures of gorillas are iconic. Another example that highlights both natural emergence and ease of iconic gesture use is an observation made by Goldin-Meadow and Feldman (1977). They observed

communication formation of linguistically deprived deaf children who were unable to acquire oral language naturally and who were not exposed to a standard manual language. They reported that children spontaneously refer to things by using iconic gestures. All these results suggest a tight and natural relationship between gesture and thought. If this is so, then experimental manipulations of the content of thought should have direct and measurable effects on gesture.

We show experimental evidence for this connection in Experiment 1. Participants were asked to read and retell the story to their children. A story was about either a carp, which was expected to induce more gesture that engages a hand held in a vertical position or a stingray, which was expected to induce more gesture that engages a hand held in a horizontal position. If mental representations are reflected in our gesture use, then we should expect these different gesture patterns across participants who read the same story about the two different fishes. Moreover, Experiment 1 also serves as baseline measure of gesture production with a normal speech rate. This baseline was used to manipulate participants' speech rate in Experiment 2.

Gesture as motor overflow

The second idea that gestures result from an overflow in the motor program for speech is not one that has received much empirical attention, nor one that has been well specified theoretically. However, this idea suggests that amount of motor activity in speaking should have direct influences on amount of gestures, and this should be thought so independently of the content of speech. Accordingly, to test this idea, in Experiment 2, we entrained speech to either a slow or fast metronome. Do gestures decrease when people speak at slower than normal rates? Do gestures increase given the faster rate of speaking? They should if gestures reflect motor overflow. Finally, does rate of speech influence rate of gesture independent of content? An affirmative answer would suggest two independent driving forces behind gesture: the meaningful content of thought and arousal.

Experiment 1

Method

Participants Twenty mothers and their children whose ages ranged from 26 to 61 months participated in the study.

Procedure Participants were assigned to either the Carp condition or the Stingray condition. The difference in the manipulation between the conditions was a kind of fish used as a hero of the story. Parents were presented with a sheet of paper, which contained either a carp story or a stingray story and were asked to

read and retell the story from memory to their child. Participants were also asked to have the child tell the story back to them. While participants were retelling a story, the aspects of their story telling were recorded by a video camera for a later coding. The story used in the study is provided in Table 1.

Result

Each parent's session was coded for several variables: all gestures, two target hand positions and speech rates. All variables were measured as rates, that is, production per minute. In order to code for these variables, the video was played in slow motion; the exact times that a hand movement began and ended were coded. Two target hand positions were counted. The "Carp-swimming" gesture consisted of holding the hand flat palm perpendicular to the horizontal table surface and the "Stingray-swimming" gesture was defined as a gesture in which the hand was flat palm down parallel to the horizontal surface of the table. These gestures were coded as either corresponding or non-corresponding gestures depending on whether the hand position corresponds to the fish in the assigned story (e.g., a carp gesture given a carp story was corresponding gesture and a stingray gesture given a carp story was a non-corresponding gesture.) All gestures were independently scored by two observers.

Participants produced gestures (target gestures plus all other gestures) at a rate of 4.1 gestures per a minute. However, as shown in Figure 1, participants produced more target gestures that corresponded to the story than gestures that did not correspond. In addition, storytellers held their hands in a horizontal position more often when telling the story about the stingray than when telling one about a carp. Finally, the average speech rate was 141.0 words per a minute.

Experiment 2

Method

Participants Twenty mothers and their children whose ages ranged from 23 to 60 months participated in the study.

Procedure The procedure was the same as that of Experiment 1 with an exception. Participants were assigned to one of four conditions: Carp condition, fast metronome, Carp condition with slow metronome, Stingray condition with fast metronome and Stingray condition with slow metronome. The speeds of the metronome were selected based on the average speech rate observed in Experiment 1. Since the normal speech rate in Experiment 1 was 140 words per a minute, we selected 150 beats per a minute for the Fast condition and 80 beats per a minute for the Slow condition. We were conservative in attempting to entrain speech to a

faster rate in this first entraining experiment in an effort to maximize our success in entraining speech. The parent storytellers were not told about the purpose of the metronomes, but were instead told to ignore them. The task of individual participants was identical to that of Experiment 2.

Table

Table 1: Story used for the study: The Adventures of (Carl the Carp / Steve the Stingray)

(Carl the Carp / Steve the Stingray) was a happy, friendly (carp with a round, silver body, big, round eyes, and a flowing, fan-like tail / stingray with a flat, gray body, beady black eyes, and a long, whip-like tail) who loved swimming with his other (carp / stingray) friends. They especially liked swimming into the depths of the water and returning to the surface. One day, when (Carl the Carp / Steve the Stingray) and his friends were enjoying another adventure in the depths of the water, they sensed some danger. They were eating lunch when, all of a sudden, there was a giant shadow looming over them. (Carl the Carp / Steve the Stingray) turned around, but it was too late! He found himself inside the belly of a big fish. He thought to himself, "This is the end of (Carl the Carp / Steve the Stingray). I'll never be able to swim around with my (carp / stingray) friends and have fun again." Just as he was thinking this, he heard a loud rumbling and was pushed out from the fish's stomach. His friends, who had been hiding in the rocks, swam cautiously towards him to make sure he was okay. "(Carl / Steve)," one of his friends said, "that big fish just burped you up! Are you all right?" "Yes," a relieved (Carl the Carp / Steve the Stingray) said, "I'm fine. Let's finish our adventure." Then, (Carl the Carp / Steve the Stingray) and all of his (carp / stingray) friends swam happily off for another fun adventure.

Results

First, we did successfully manipulate speech rate, $t = -2.44$, $p < .05$. The average number of words per minute was 145.5 in the Fast condition and 120.0 in the Slow condition. Second, as can be seen in Figure 2, participants produced more gestures per a minute in the Fast condition than they did in the Slow condition. This indicates that gesture production is tied to speech rate.

As shown in Figures 3 and 4, content effects are seen in the both Fast and Slow conditions, but the effect is reliable only in the Fast condition (for Fast condition; $t = 2.198$, $p < .05$, and for Slow condition; $t = 1.405$, $p =$

.18.) Participants in both Fast and Slow conditions produced more gestures that corresponded to the story that they retold than gestures that did not correspond. The fact that speech entrained to a slow metronome, 80 beats per a minute, decreases gesture use and weakens the content effect on iconic gestures suggests a direct link between arousal and content.

Discussion

The two experiments yield 3 main results. First, the content of thought directly influences hand position. Thinking about carps leads one to holds one's hand perpendicular to the tabletop. Thinking about stingrays leads to hands held in a horizontal position over the table. By experimentally manipulating the content of thought, one manipulates hand position. This is consistent with the proposal that gestures iconically represent meaning. Second, speech and gesture are readily entrained to a rhythmic beat. And, faster rates of speech lead to more gestures and slow rates of speech lead to fewer gestures. This is consistent with the idea of gestures emerging as a consequence of arousal. Amount of energy appears to be is a driving force in gesture. Third, arousal (or rate of speech) appears linked to the frequency of iconic gestures. This suggests, contrary to the motor overflow hypothesis, that the relevant activation concerns meaningful content and not just the speech motor plan. High activation leads to more iconically related gestures as if high arousal leads to more highly activated meanings that emerge in both spoken words and in meaning related gestures.

Abstract

One critical step in addressing and resolving the problems associated with human errors is the development of a cognitive taxonomy of such errors. In the case of errors, such a taxonomy may be developed (1) to categorize all types of errors along cognitive dimensions, (2) to associate each type of error with a specific underlying cognitive mechanism, (3) to explain why, and even predict when and where, a specific error will occur, and (4) to generate intervention strategies for each type of error. Based on Reason's (1992) definition of human errors and Norman's (1986) cognitive theory of human action, we have developed a preliminary action-based cognitive taxonomy of errors that largely satisfies these four criteria in the domain of medicine. We discuss initial steps for applying this taxonomy to develop an online medical error reporting system that not only categorizes errors but also identifies problems and generates solutions.

1. Introduction

The medical error report from the Institute of Medicine (Kohn, Corrigan, & Donaldson, 1999) has greatly increased people's awareness of the frequency, magnitude, complexity, and seriousness of medical errors. As the 8th leading cause of death in the US with 98,000 preventable deaths per year, ahead of motor vehicle accidents, breast cancer, or AIDS, medical errors need immediate attention from academic, healthcare, and government institutions and organizations. To achieve the goal of reducing medical errors by 50% in five years set by the former Clinton Administration, we need to understand the fundamental causes of medical errors such that medical errors can be prevented or greatly reduced systematically at a large scale. In our opinion, cognitive factors are fundamental in medical errors. This can be seen from the view of the healthcare system hierarchy and the view of action chains.

Cognitive factors are critical at various levels of the healthcare system hierarchy of medical errors (Figure 1). At the lowest core level, it is individuals who trigger errors. Cognitive factors of individuals play the most critical role here (Reason, 1992). At the next level, errors can occur due to interactions between an individual and technology. This is an issue of human-computer interaction where cognitive properties of interactions between human and technology affect and sometimes determine human behavior (Helander, Landauer, & Prabhu, 1997; Zhang, 1997;

Zhang & Norman, 1994). At the next level, errors can be attributed to the social dynamics of interactions between groups of people who interact with complex technology in a distributed cognitive system. This is the issue of distributed cognition and computer-supported cooperative work (Baecker, 1993; Hutchins, 1995a, 1995b; Zhang, 1997). At the next few levels up, errors can be attributed to factors of organizational structures (e.g., coordination, communications, standardization of work process), institutional functions (e.g., policies and guidelines), and national regulations. At these higher levels, cognitive factors also play some roles. Although the properties at the six levels can be to some extent studied independently, a cognitive foundation for the system is essential for a complete and in-depth understanding of medical errors.

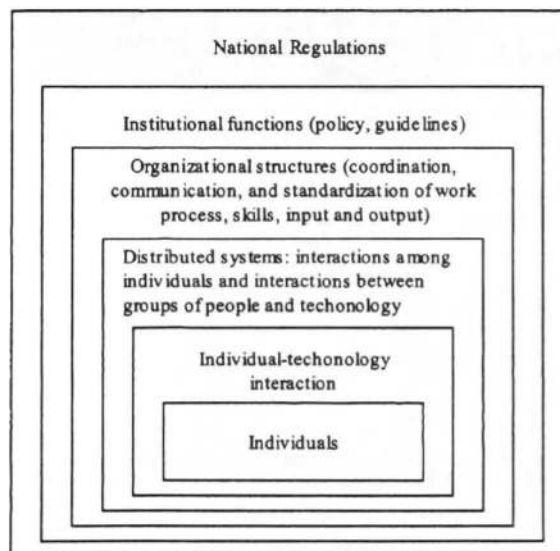

Figure 1. The system hierarchy of human errors in medicine

From the view of action chains, the critical roles of cognitive factors in medical errors are also clear. Figure 2 shows the chain of events and factors that lead to an error in a system. It is clear that individuals are at the last stage of the chain, although the individuals may not be the root cause of the error. If the chain of events can be stopped at the in-

dividual's stage through cognitive interventions, errors could be potentially prevented.

Medical errors are human errors in healthcare. By definition (Kohn et al., 1999; Reason, 1992), human errors are errors in human actions. Human actions are primarily cognitive activities. It is not surprising to see that human errors occur primarily due to inadequate information processing in cognitive tasks (Bogner, 1994; Norman, 1981; Reason, 1992; Woods, Johannesen, Cook, & Sarter, 1994). In order to prevent or greatly reduce medical errors, it is critical to understand the underlying cognitive mechanisms of medical errors.

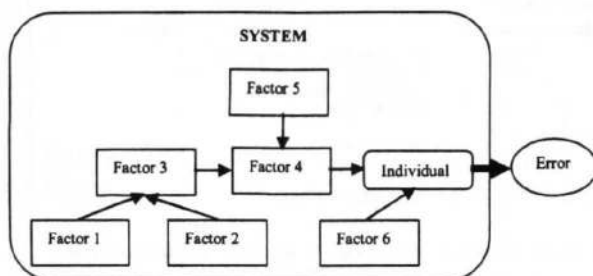

Figure 2. The chain of events leading to an error

2. Theoretical Background

To understand the cognitive mechanisms underlying medical errors, we first need to develop a cognitive taxonomy of medical errors that can (1) categorize all types of medical errors along cognitive dimensions, (2) associate each type of medical error to a specific underlying cognitive mechanism, (3) explain why and even predict when and where a specific error will occur, and (4) generate intervention strategies for each type of error.

The purpose of this paper is to develop an action based cognitive taxonomy that can be potentially expanded to include all four features listed above.

2.1. Reason's definition of human error

Reason's (Reason, 1992) definition of human error is the most widely accepted: an error is a failure of achieving the intended outcome in a planned sequence of mental or physical activities. According to Reason, human errors are divided into two major categories: (1) slips that result from the incorrect execution of a correct action sequence and (2) mistakes that result from the correct execution of an incorrect action sequence. In comparison with mistakes, slips have been extensively studied and better understood (for reviews, see Norman, 1986; Reason, 1992).

2.2. Norman's action theory

To be comprehensive, descriptive, predictive, and generalizable, a cognitive taxonomy should be based on a

sound cognitive theory that has explanatory and predictive power. Since human errors are defined as errors in human actions, a cognitive theory of human actions can provide the theoretical foundation for the cognitive taxonomy. In our opinion, the cognitive theory of human action most appropriate for medical errors is the seven-stage action theory developed by Norman (Norman, 1986, 1988) and refined by Zhang and colleagues (Zhang, 1987; Zhang, Patel, & Johnson, in press). The seven-stage action theory is shown in Figure 3, with a demonstration showing the action of deleting a file on a DOS system. According to this theory, any action has seven stages of activities: (1) establishing the goal (e.g., "delete file"); (2) forming the intention (e.g., "use remove command"); (3) specifying the action specification (e.g., "remove ../home/paper/talk_old.ver1"); (4) executing the action (e.g., "typing command text, hit return"); (5) perceiving the system state (e.g., "prompt symbol :>, no feedback"); (6) interpreting the state (e.g., "nothing happened"); and (7) evaluating the system state with respect to the goals and intentions (e.g., "form sub-goal to find out current state of the system").

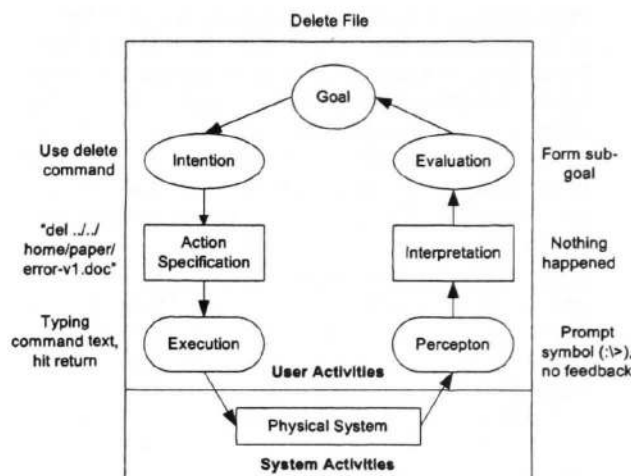

Figure 3. Norman's seven-stage theory of action.

3. The Cognitive Taxonomy

Reason developed one taxonomy of human errors (Reason, 1992); however, it was not based on a systematic theory of human action; it was primarily for slips, not for mistakes; and it has not been systematically applied to medical settings. Norman's (Norman, 1986) seven-stage action theory was developed for the study of human-computer interaction and the design of user interfaces—it has not been applied to the study of errors.

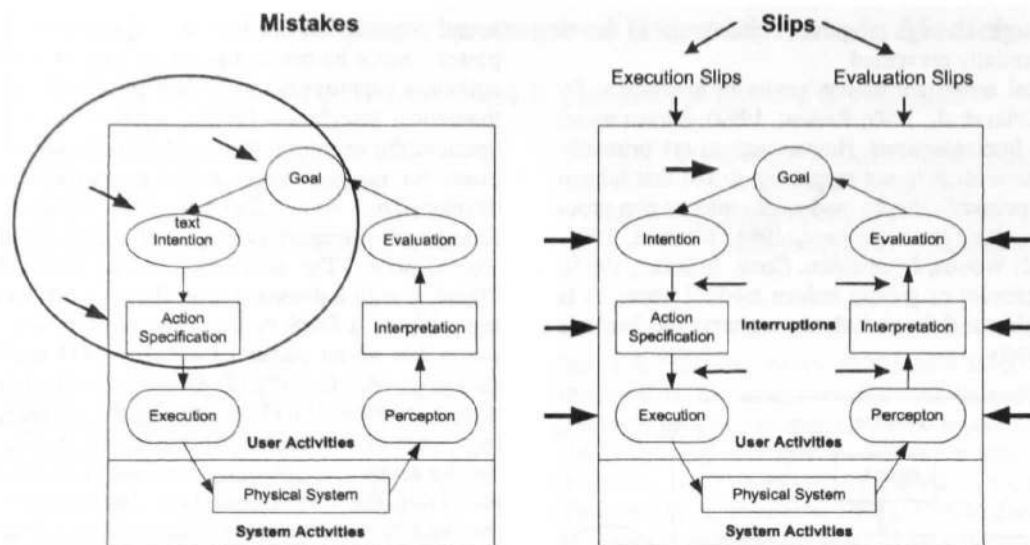

Figure 4. Slips can occur at all stages, whereas mistakes can only occur at the first three stages.

The cognitive taxonomy we develop here is an application and extension of Norman's action theory to the categorization of medical errors. It is an action-based cognitive taxonomy. This taxonomy covers all types of human errors, because a human error is an error in an action and any action has to go through the seven stages. According to our taxonomy, errors can occur at any of the seven stages of action and between any two adjacent stages: due to incorrect translation from goals to intentions, incorrect action specifications from intentions, incorrect execution of actions, misperception of system state, misinterpretation of data perceived, and misevaluation of interpreted information with regard to the goal of the task. Unlike other taxonomies, our taxonomy specifies the places where mistakes and slips may occur (Figure 4). A slip is the incorrect execution of a correct action sequence. Slips can occur at all seven stages of action and between stages. Mistakes, however, can only occur at the first three stages of action because a mistake is the correct execution of an incorrect action sequence and only the first three stages can contribute to the formation of an incorrect action sequence.

3.1. Slips

Under our cognitive taxonomy, slips can be divided into execution slips and evaluation slips (see Figure 4 and Table 1).

Execution slips are associated with the execution of an action. They occur at stages of Goal, Intention, Action Specification, and Execution. For the slips at each stage, there are corresponding cognitive mechanisms. A correct goal could be distorted due to its strongly shared schema with another irrelevant goal. A correct intention could be deactivated due to

memory decay or swapped by another irrelevant intention due to similarity of schemas. A correct action specification could be distorted due to many factors such as attention shift, situational stimulation, etc. The execution of an action sequence could misfire due to memory and attention problems or various environmental factors. Table 4 shows a list of possible cognitive mechanisms for slips at each of the stages.

Similarly, evaluation slips are associated with the evaluation of the outcomes of an action. They occur at the stages of Perception, Interpretation, and Evaluation. There are also corresponding cognitive mechanisms associated with the slips at each of these stages. The outcome of an action might be impossible to perceive, hard to perceive, or perceived in an incorrect way. The interpretation stage may also induce errors due to prior knowledge, lack of context, or as a direct result of misperception. The evaluation stage may fail due to insufficient feedback, delayed feedback, information overload, memory failure, and other factors.

Table 1 shows not just the types of slips under the cognitive taxonomy but also examples of slips in each category and potentials solutions that can prevent the slips from happening.

3.2. Mistakes

Under our cognitive taxonomy, mistakes are categorized into goal mistakes, intention mistakes, and action specification mistakes. These correspond to the first three stages in the action cycle where mistake can occur. Goal mistakes and intention mistakes are mostly knowledge-based mistakes, such as faulty conceptual knowledge, incomplete knowledge, biases and faulty heuristics, incorrect selection of knowledge, information overload, etc. Action specification mistakes are

mostly rule-based mistakes, such as misapplication of good rules, encoding deficiencies in rules, action defi-

ciencies in rules, dissociation between knowledge and rules, etc.

Table 1. An Action Based Cognitive Taxonomy: Slips

	Stage in Action Cycle	Examples	Cognitive mechanisms	Potential solutions
Execution Slips	Goal slips	<i>A doctor was called out of the room to answer an urgent call and afterwards he went to the room of a different patient who was next in the queue. (Loss of activation)</i>	<ul style="list-style-type: none"> •Loss of activation •Cross talk (concurrent) •Cross talk (sequential) •Altered goal •Delayed activation •Overflow of goal stacks 	<ul style="list-style-type: none"> •Provide memory aids •Reduce multitasking •Reduce interruptions •Reduce goal stacks •Train users
	Intention Slips	<i>"I went into my bedroom intending to fetch a book. I took off my rings, looked in the mirror and came out again—without the book." (Loss of activation)</i>	<ul style="list-style-type: none"> •Loss of activation •Cross talk (concurrent) •Cross talk (sequential) •Reversal of schema •Activation of incorrect schema 	<ul style="list-style-type: none"> •Provide memory aids •Reduce multitasking •Situating actions •Reduce interruptions
	Action Specification Slips	<i>IL-11 (Oprelvekin, or Interleukin-eleven) was misinterpreted as IL-2 (Aldesleukin, or Interleukin-two). 11 was read as the Roman numeral two. (Associative activation)</i>	<ul style="list-style-type: none"> •Associative activation •Failure of retrieval •Sequence mutation •Situating activation •Description •Cross talks 	<ul style="list-style-type: none"> •Automation •Decision support •Situating actions •Train users •Direct action
	Execution slips	<i>"I meant to turn off the antibiotics IV only, but turned off the infusion pump completely." (Double capture)</i>	<ul style="list-style-type: none"> •Capture •Double capture •Perceptual confusion •Deviation of motor skills •Misfiring •Omission 	<ul style="list-style-type: none"> •Automation •Visualization •Display design •Reduce interruption •Memory aids
Evaluation Slips	Perception slips	<i>A patient died of liquid aspiration. Because the water trap connected with a tube had no mechanism to protect against reflux to patient's trachea, and there was no feedback in the system. (Lack of perception)</i>	<ul style="list-style-type: none"> •Lack of perception •Misperception •Mis-anticipation 	<ul style="list-style-type: none"> •Direct perception •Immediate feedback
	Interpretation slips	<i>A yellow flashing light on a medical device was interpreted as non-critical when it really meant critical. (Misinterpretation)</i>	<ul style="list-style-type: none"> •Misinterpretation •Default schema •Confirmation bias •Information overload •Loss of memory 	<ul style="list-style-type: none"> •Display design •Decision support •User training •Memory aids •Situation awareness
	Evaluation slips	<i>A nurse repeated radiation therapy to a patient three times in a row, due to poor feedback. The patient died three months later. (Lack of feedback)</i>	<ul style="list-style-type: none"> •Lost goal •Insufficient information •Evaluating different goal •Information overload •Lack of feedback 	<ul style="list-style-type: none"> •Memory aids •Display design •Action tracking •Information reduction

Table 2. An Action Based Cognitive Taxonomy: Mistakes

	Stage in Action Cycle	Examples	Cognitive Mechanisms	Potential solutions
Knowledge-based Mistakes	Goal mistakes	<i>Stick with a diagnosis that was generated through a large investment of time and effort even if there was evidence indicating other possibilities. (Biases)</i>	<ul style="list-style-type: none"> • Misdiagnosis • Faulty conceptual knowledge • Incomplete knowledge • Biases • Faulty heuristics 	<ul style="list-style-type: none"> • Training • Education • Representational Aid • Decision support
	Intention mistakes	<i>A physician treating a patient with oxygen set the flow control knob between 1 and 2 liters per minute, not realizing that the scale numbers represented discrete, rather than continuous, settings. (Incorrect knowledge)</i>	<ul style="list-style-type: none"> • Incorrect selection of knowledge • Misapplication of knowledge • Information overload • Incorrect knowledge 	<ul style="list-style-type: none"> • Training • Education • Decision support • Information reduction • Display design • Representational Aid
Rule-based Mistakes	Action Specification mistakes	<i>Strange burn scars appeared in post-operative patients in a hospital. The problem was caused by electric discharge of the device that was not grounded. The device has a blinking red to signal for the problem, but the device operators did not know the meaning of the signal. (Incomplete knowledge)</i>	<ul style="list-style-type: none"> • Misapplication of good rules • Encoding deficiencies in rules • Dissociation between knowledge and rules • Action deficiencies in rules • Incomplete knowledge 	<ul style="list-style-type: none"> • Decision support • Automation • User training • Representational Aid

Table 2 shows not only the types of mistakes under the cognitive taxonomy but also examples of mistakes in each category and potentials solutions that can prevent the mistakes from happening. In comparison with slips, mistakes are more complex and less understood.

Most studies about mistakes in the past were byproducts of studies of reasoning biases and heuristics in decision-making tasks (Hogarth & Einhorn, 1992; Tversky & Kahneman, 1974). Recently there have been a growing number of studies that explicitly examine various types of mistakes in medicine (Patel & Kaufman, 2000; Patel, Lloyd, & Melanson, 2000; Patel & Ramoni, 1997). We expect to see more studies of this kind and we will expand our taxonomy to accommodate new data and theories.

4. Discussion and Conclusion

One critical step towards reducing medical errors in particular and human errors in general is a cognitive

taxonomy of errors that can (1) categorize all types of medical errors along cognitive dimensions, (2) associate each type of medical errors to a specific underlying cognitive mechanism, (3) explain why and even predict when and where a specific error will occur, and (4) generate intervention strategies for each type of error. Based on Reason's (Reason, 1992) definition of human errors and Norman's (Norman, 1986) cognitive theory of human action, we developed a preliminary action-based cognitive taxonomy of medical errors that to some extent satisfy these four criteria. Our taxonomy can categorize all types of errors (slips and mistakes) according the stages of the action cycle. We have identified a set of cognitive mechanisms (though not exhaustive) that underlie each type of slip or mistake. Our taxonomy can also explain why a specific error occurs, although we have not developed the taxonomy in enough detail to make predications on when and where an error will occur. Finally, at a high and conceptual

level, we have generated a set of possible solutions addressing each type of errors.

One important practical implication of the cognitive taxonomy of medical errors is that it can provide systematic, principled methods for the design of medical error reporting systems. Current medical error reporting systems are mostly based on free text in an unstructured format. Medical error data collected in this way are rarely useful for the detection of patterns, discovery of underlying factors, and generation of solutions, because user entered free text do not contain the right types of information needed for interventions and is difficult to analyze in a systematic way. Medical error reporting systems should not be merely record keeping systems. They should be systems for the identification of problems and generation of solutions. We are currently developing an online medical error reporting system that is based on the cognitive taxonomy we have been developing. In this system, questions and inquiries are generated to encode cognitively relevant information; the categorization of errors is along relevant cognitive dimensions; and it is designed to generate immediate recommendations on possible intervention strategies.

Why do metaphors seem deeper than similes?

Abstract

Figurative expressions in metaphor form (e.g., *Marriage is a journey*) seem stronger and deeper than expressions in simile form (e.g., *Marriage is like a journey*). We ran a study to examine the nature of these judgments. Participants read short paragraphs describing either object attributes or relational structure and then made a forced choice of the grammatical form of a figurative expression mentioning the target concept referred to in the passages. The results showed that the metaphor form was chosen more often (1) for expressions with conventional bases, and (2) when figurative statements followed contexts containing relational information. We speculate about a possible linkage between conventionalization and relationality.

Introduction

Nominal figurative statements can be expressed in two ways – in simile form (*X is like Y*) and in metaphor form (*X is Y*). Although the two grammatical forms largely serve the same purpose (showing that one entity is figuratively similar to another), people report that expressions in metaphor form feel more profound and express stronger claims than expressions in simile form. For example, saying *Her heart is a stone* feels deeper than *Her heart is like a stone*. Further, several studies (Gibb & Wales, 1990; Bowdle, 1998; Aisenman, 1999) have found that if people are asked to make a choice between an expression in metaphor form or the same expression in simile form, the simile form is chosen more often. It appears that people are more conservative in using metaphors than in using similes.

The greater force of the metaphoric form was noted by Glucksberg and Keysar (1990), who proposed that the metaphor form is the basic form of figurative statements and that similes are understood as variants of metaphors. Noting that the grammatical form of metaphors matches that of category inclusion statements, they suggested that metaphors in fact function as category inclusion statements, where the category is an abstraction that can be accessed or created from the metaphor's base concept. (We will use the terms *target* and *base*, respectively, for the X and Y

terms, of a figurative expression *X is [like] Y*.) There has been debate concerning the processing implications of this theory, but for our purposes the key point is Glucksberg and Keysar's insight that the grammatical form of figurative statements has psychological force, with metaphor being the stronger, more categorical form. This paper examines the reasons for this phenomenon.

Two recent theories have proposed different explanations for the simile-metaphor difference. One account singles out the conventionality of the base term; the other, the relationality/attributionality of the metaphor's interpretation. The first account, the Career of Metaphor hypothesis (Bowdle & Gentner, 1999; Gentner & Bowdle, 2001) suggests that the difference lies in the conventionality of the base term: figuratives with conventional bases are expressed as metaphors, and those with novel bases are expressed as similes. The second account, Aisenman's (1999) Relational Precedence hypothesis, suggests that the difference is due to the kind of interpretation the expression receives: relational interpretations are stated as metaphors, and attributional interpretations are stated as similes.

In their research on metaphor processing, Gentner and Wolff (1999) proposed an important distinction between newly minted figuratives and conventionalized figuratives. According to the Career of Metaphor hypothesis, figuratives with novel bases, such as *An encyclopedia is (like) a uranium mine*, are processed by comparison between the target and the literal meaning of the base. In contrast, figuratives with conventional bases, such as *An encyclopedia is a goldmine*, can be processed by alignment with a conventional abstraction (e.g., *a source of something valuable*) associated with the base term. The key difference between novel and conventional bases is that the representations of conventional bases include a secondary metaphoric meaning along with the original literal meaning. They have become polysemous. In contrast, representations of novel bases contain only a literal meaning.

Gentner and Wolff (1997) proposed that conventional metaphoric meanings are created over time as a result of repeated comparisons of different

target terms with the same base. The idea is that through progressive alignments of the base, a set of properties or a relational schema belonging to the base emerges as a separable abstraction. This can become an additional word sense – a kind of metaphoric category associated with the base.

Bowdle's Grammatical Concordance principle links the Career of Metaphor hypothesis with the simile-metaphor distinction. It states that metaphoric expressions are interpreted by the process of structural alignment (Gentner & Markman, 1997), but the nature of the invited alignment differs for metaphors and similes. The simile form invites directly aligning the literal base and target concepts (e.g., *encyclopedia* and *gold mine* in the above example), whereas the metaphor form suggests that the listener should first access the abstraction associated with the base – e.g., *source of something valuable* – and then align it with the target representation. Consistent with this explanation, Gentner and Bowdle (2001) found that novel metaphors are slow to process. This follows from the claim that such statements lead to a false start in processing. For example, hearing *That encyclopedia is a uranium mine* is infelicitous, because there is no conventional abstraction associated with uranium mines.

Thus, the claim is that (1) repeated alignments can lead to the formation of an abstraction, and (2) figurative statements can occur in metaphor form only when there is existing abstraction (or metaphorical category) associated with the base. Perhaps the most striking evidence for this claim is Bowdle's (1998) study showing 'in vitro' conventionalization. After seeing novel bases in parallel comparisons with three target terms in simile form, subjects preferred to express further statements involving that base in metaphor form. They also (mis) recalled the statements they had seen as having been in metaphor form. Gentner and Bowdle (2001) found that as figurative statements became increasingly conventional, there is a shift in people's preference from the simile form to the metaphor form.

A second explanation for the subjective differences in perception of similes and metaphors was recently offered by Aisenman (1999). She extended Gentner's (1988; Gentner & Clement, 1988) distinction between attributional and relational comparisons and suggested that people primarily use the metaphor form to highlight common relations between the base and target, and the simile form to highlight common attributes (Aisenman, 1999). Thus, the metaphor form is likely to convey a deep common system of relations. This theory fits well with the intuition that metaphors often seem more profound than similes. In her study, Aisenman presented subjects with base and target terms and asked whether they would be more likely to put sentences with those terms in simile or metaphor form.

When the base and target shared mostly surface attributes (e.g., *The sun is (like) an orange* – both are round and orange), participants preferred to state sentences in simile form. When the base and target shared common relational structure (e.g., *Television is (like) a magnet* – both attract), participants were more likely to use the metaphor form. Aisenman's results suggest that the metaphor form is preferred for relational commonalities.

There are thus two accounts for form differences in figurative language: metaphors tend to be preferred over similes (a) when the base is conventional or (b) when the interpretation is relational. To compare these accounts, we varied both factors – conventionality of the base and the type of commonalities between the base and target – and obtained people's preferences for stating figurative expressions in simile or metaphor form.

Experiment 1. Context Priming

We selected 20 metaphors from prior metaphor studies (Ortony, 1979; Gentner & Clement, 1988; Aisenman, 1999). The metaphors used were classified as double metaphors (Gentner & Clement, 1988) in that they permitted both attributional and relational interpretations. We presented subjects with short paragraphs describing the target, focusing either on its attributes or on its relational structure. Examples of relational and attributional contexts are listed in Table 1. Then, participants were asked to choose which of the two figurative sentences they preferred. Both sentences featured the target coupled with the same base and differed only in that one of them was a simile and one was a metaphor. Half the bases were novel, and half were conventional. Conventionality of the base was operationalized as having the metaphoric meaning listed in the Merriam-Webster Collegiate dictionary. The base terms never appeared in the contexts preceding the simile and metaphor statements. Table 1 shows a sample stimulus with a conventional base.

The Career of Metaphor account predicts that people would be more likely to prefer the metaphor form for statements with conventional rather than novel bases. Aisenman's Relational Precedence hypothesis predicts that people would be more likely to prefer the metaphor form when given the paragraph priming the relational interpretation.

Method

Sixty-four Northwestern University undergraduates were presented with 20 short paragraphs. Each paragraph supported either an attributional or relational interpretation of a figurative expression. After reading the paragraph, participants chose between simile and metaphor forms as shown in Table 1 and were asked to choose the sentence they preferred by circling it. Four

random orders were used across participants. Whether the sentence in simile or metaphor form was presented on the left side of the page was counterbalanced.

Table 1: Example of attributional and relational contexts

Conventional base	
<u>Attributional interpretation:</u>	
Mr. White, a sociologist, is writing an article about poverty in urban America. He considers poverty a horrible blight on our society and argues that the government must intervene with a welfare reform. He thinks that	
Poverty is a disease.	Poverty is like a disease.
<u>Relational interpretation:</u>	
Mr. White, a sociologist, is writing an article about poverty in urban America. He considers poverty to be increasing and argues that, unless the government intervenes with a welfare reform, poverty will spread further. He thinks that	
Poverty is like a disease.	Poverty is a disease.

Results

We computed the number of metaphor choices by coding preference for simile form as 0 and preference for metaphor form as 1. Analysis of variance performed with base conventionality and context type as between-subjects factors showed a significant effect of base conventionality ($F_{1, 39} = 7.50$, $MSE = 0.31$, $p < 0.01$). The proportion of metaphor form choices was significantly higher for statements with conventional bases ($M_C = 0.39$) than for statements with novel bases ($M_N = 0.22$). The number of metaphor preferences was significantly lower than chance for both novel and conventional bases ($p < 0.05$).

We also obtained a marginally significant effect of preceding context type ($F_{1, 39} = 3.66$, $MSE = 0.15$, $p = 0.06$). Statements following relational contexts were preferred in metaphor form more often than statements following attributional contexts ($M_R = 0.37$, $M_A = 0.24$). The number of metaphor preferences was significantly lower than chance for both relational and attributional contexts ($p < 0.05$). The results are summarized in Figure 1.

The preference for metaphoric form for relational information was only marginally significant. However, an item analysis indicated a disparity in the quality of the items used. Some items were strongly preferred in simile form (e.g., only one out of 64 participants chose to put *Titanium chips are (like) diamonds* in metaphor form). It thus seemed possible that not all the items were suitable as metaphors. To ensure that the Relational Precedence view was fairly tested, we

removed items that were put in metaphor form by less than seven participants (2 with novel bases and 2 with conventional bases). An ANOVA performed on the remaining items yielded a significant effect of context type ($F_{1, 31} = 5.10$, $MSE = 0.16$, $p < 0.05$) in addition to the significant effect of base conventionality ($F_{1, 31} = 10.15$, $MSE = 0.32$, $p < 0.01$). The interaction between base conventionality and context type was not significant.

Figure 1: Proportion of metaphor choices for novel and conventional bases. Error bars show standard error.

Experiment 2

The results of the first study offered support for both the Career of Metaphor account – in which the metaphor-simile distinction is one of conventionality – and the Relational Precedence hypothesis. However, one concern here is to what extent the results simply reflect the nature of the materials. First, although the figurative expressions used in Experiment 1 allow both relational and attributional interpretations, it is possible that people may prefer one kind of interpretation over the other. Previous studies have demonstrated that people find relational interpretations of figurative expressions more interesting and apt (Clement & Gentner, 1988). Second, and more importantly, it is possible that the conventional metaphors we used were biased in favor of either relational or attributional interpretations, relative to the novel metaphors.

To calibrate the materials, we gave the figurative expressions used in Experiment 1 to a new group of participants, either in simile or metaphor form, and asked the participants to rate how much they agreed with the relational and attributional interpretations. Both interpretations were shown together for each figurative statement, but participants rated each

separately. Thus they were free to assign high or low ratings to both the relational and attributional interpretations if they chose.

Method

Thirty-two Northwestern University undergraduates were presented with 28 statements: 20 figurative statements taken from Experiment 1, and 8 fillers. The statements were blocked so that each participant saw either all statements in simile form or all statements in metaphor form. Two random orders were used. After each statement, a relational and attributional interpretations of the statement appeared. The order of the interpretations on the page was counterbalanced. The participants were asked to rate how much they agree with each of the interpretations on a 1 to 7 scale.

Results

We computed the scores for the relational and attributional interpretations for each item. Table 2 shows mean ratings for each of the four item categories, along with the number of relational and attributional interpretations that received ratings of 4 or greater (out of 7). Consistent with prior research, relational interpretations are preferred over attributional interpretations overall (Gentner, 1988; Gentner & Clement, 1988).

The key question for our purposes is whether the materials were skewed such that conventional metaphors had more or better relational interpretations than the other categories. This does not appear to be the case. Relational interpretations received high ratings (4 or above) for 8 out of 10 items in each of the four item categories -- conventional metaphors, novel metaphors, conventional similes, and novel similes. (Attributional interpretations were rated lower overall, as shown in Table 2.) It appears that the intended relational interpretations were highly apt for both metaphor and simile forms. These data offer some reassurance that the shift towards relationality in metaphor preference was not simply determined by disproportionate availability of relational interpretations for metaphors over similes.

We also created a relational preference score (R_{pref}), which was the difference between the relational rating and the attributional rating. An analysis of variance with base conventionality (novel or conventional) and grammatical form (simile or metaphor) as between-subjects factors revealed no significant differences in relational preference scores ($F_{3, 636} = 1.25$, $MSE = 13.07$, $p < 0.3$).

Table 2. Mean interpretation ratings and number of interpretations that received high ratings (in parentheses)

	Attributional	Relational
Conventional		
Metaphor	3.81 (5)	4.95 (8)
Simile	4.35 (6)	4.74 (8)
Novel		
Metaphor	3.68 (4)	4.51 (8)
Simile	3.81 (4)	4.78 (8)

Discussion

As predicted by the Career of Metaphor hypothesis, participants in Experiment 1 were likely to choose the metaphor form for figurative statements with conventional bases, and the simile form for those with novel bases. Aisenman's Relational Precedence hypothesis also received support: the metaphor form was chosen more often for relational meanings (i.e., following a relational context) than for attributional meanings (following an attributional context).

Might both claims be true? Some intriguing possibilities arise if we consider the implications of these two patterns taken together. Suppose that, as in the Career of Metaphor hypothesis, nominal figurative expressions are initially phrased as similes. As these expressions become conventionalized, the metaphor form becomes more felicitous. Suppose further that relational meanings of novel bases have more potential to get conventionalized. Then we would find a preponderance of relational meanings among conventional bases. An informal survey of the literature using conventional metaphors suggests that most of them do convey relational meanings. For example, the metaphors used by Ortony (1979) and by Glucksberg and Keysar (1990) are primarily relational (e.g., *Cigarettes are time bombs*; *Some jobs are jails*; *Sermons are sleeping pills*). Assuming that these stimuli are roughly typical of conventional metaphors, we might speculate that there is a preponderance of relational figuratives within the class of conventionalized metaphors. How might such a link between relationality and conventionality have come about?

One possibility is that different forms are used for conventionalized relational and attributional figurative statements. English has a special form for conventional bases that is often used for property attribution -- "as X as Y," where X is the shared attribute, and Y is the base term -- for example, *as white as snow*; *as strong as an ox* (Ortony, 1979). Perhaps conventional attributional meanings are siphoned off by this dedicated form.

However, relational adjectives can enter the *as X as Y* frame as well (e.g., *as delicious as an apple*; *as fierce as a tiger*). The only requirement for the descriptor *X* seems to be that it be orderable on some dimension. Thus a possible special form for attributive figuratives does not seem like a viable explanation for the preponderance of conventional relational metaphors.

Another possibility is preemption by existing terms. Over the course of development, languages have developed names for attributes, which preempt the creation of new ones (Clark, 1992). On this account, creation of attributional metaphoric meanings might be less likely simply because we already have names for attributes. However, this explanation carries the hidden assumption that the number of attributes we want to express is smaller than the number of relations.

This brings us to the third and most speculative possibility. There is evidence that (1) people find shared relational structure more interesting or important than shared attributes; and that (2) relational meanings are relatively slow to emerge in cognitive development (Gentner & Rattermann, 1991; Halford, 1993) and arguably in the history of science. Applying this to the evolution of metaphor suggests that new relational abstractions are more likely to become entrenched than attribute meanings. Coherent relational systems are likely to be preserved in comparison processing, and this may carry over into the conventionalization of meanings and the formation of new categories (Gentner & Bowdle, 2001; Ramsar & Pain, 1996; Shen, 1992). On this account, a simile that expresses shared relational structure is more likely to give rise to parallels than one that expresses an attributional likeness. This would lead to differential likelihoods of conventionalization for relational and attributional figuratives.

Some evidence for this account can be obtained from studies of word meaning extension over time. One of the ways one can extend the meaning of a word is by analogy. For example, words like *bridge* and *sanctuary* initially had only concrete meanings, but now can denote metaphoric categories such as *something connecting two points* and *a safe place*, respectively. Table 3 shows the timeline of the first occurrences of the literal and figurative meanings of *sanctuary*, as listed in the Oxford English Dictionary, as well as other sample occurrences. (All senses are written exactly as in the OED.)

For *sanctuary*, the literal meaning of a holy building appears in 1340. Extensions to the church or the body of believers also appear in the 14th century. The first figurative usage appears two centuries later, in 1568. Interestingly, the first figurative use is signaled by an explicit comparison phrase "counted as a sanctuary". The first 'metaphorical' occurrence, unmarked by a comparison phrase, occurs considerably later, in 1685.

Table 3. Timeline of occurrences of literal and figurative meanings for *sanctuary*.

[Initial literal meaning]

I. a holy place – a building or place set apart for the worship of God or of one or more divinities: applied, e.g., to a Christian church, the Jewish temple and the Mosaic tabernacle, a heathen temple or site of local worship, and the like; also *fig.* To the church or the body of believers

1340...*In that sanctuary oure lord sall be kyng...*
1382 *And thei shulen make to me a seyntyuarie, and Y shal dwelle in the myddil of hem.*
1530. *Sanctuarie, a place hallowed and dedicate vnto god.*

II.a – a church or other sacred place in which, by the law of the medieval church, a fugitive from justice, or a debtor, was entitled to immunity from arrest. Hence, in a wider sense, applied to any place in which by law or established custom a similar immunity is secured to fugitives.

1374 *To whiche luge ment they nolden nat obeye but defendedyn hem by the sikernes of holy howses, that is to seyn fledden in to sentuarie.*
1463-4 *Eny persone..that shall dwelle or inhabit within the Sayntwarie and Procyncte of the same Chapell.*

[First figurative meaning]

1568 *Vsing alwaie soch discrete moderation, as the scholehouse should be counted a sanctuarie against feare.*

[First unmarked figurative meaning]

1685 *My house is your Sanctuary, and here to offer you violence, wou'd prejudice myself.*
1770 *The reformation was preceded by the discovery of America, as if the Almighty graciously meant to open a sanctuary to the persecuted in future years...*

Table 4. Timeline of occurrences of literal and figurative meanings for *bridge*.

[Initial literal meaning]

I. A structure forming or carrying a road over a river, a ravine, etc., or affording passage between two points at a height above the ground.

c1000 *theas brycg*
1131 *Men weorth on adrencte and brigges to brokene.*
c1449 *The brigge of Londoun.*
1660 *This was so severe a bill upon the Women, that, if a bridge was made from Dover to Calais, the women would all leave this kingdom.*

[Figurative]

1225 *The beoth ouer thisse worldes see, uppen the brugge of heouene.*
1742 *Faith builds a bridge from this world to the next.*
1863 *The bridge for thought to pass from one particular to the other.*
1874 *Gestures... forming the bridge by which we may pass over into spoken language.*

The pattern for *bridge*, shown in Table 4, is similar. The first literal meaning of *bridge* as a structure affording passage between two points above the ground goes back to the 11th century. However, the figurative

uses are not listed until the middle of the 18th century, except for a single reference to the bridge of heaven (which may have been meant literally) in 1225.

These patterns suggest that, at least in some cases, the more abstract, figurative meanings appear later in written language. In both cases, these figurative meanings are relational in nature. Interestingly, at least for *sanctuary*, the derived category no longer seems metaphoric; it has become a literal sense.

We suggest that the Relational Precedence account and the Career of Metaphor account may both be operative in the evolution of metaphor, and that they interact. Beginning with a pool of novel figuratives, the Career of Metaphor hypothesis states that for some of these the base term is repeatedly used in parallel comparisons, so that a conventional abstraction becomes associated with the base. What we suggest is that figurative expressions that yield coherent relational systems are most likely to be found novel and useful. Their bases are thus most likely to be reused and thereby conventionalized. For example, the simile *The cloud is like a marshmallow* elicits common attributes of the target and base, such as fluffy and white. But the potential abstraction 'white and fluffy' is unlikely to become a conventionalized word sense, both because of lexical preemption (we already have words for white and fluffy) and because the category it suggests is simply not very interesting. (Indeed, the conventional use of marshmallow as a metaphor is relational, as in *That boxer turned out to be a marshmallow*.)

Metaphors are a source of polysemy in language – they allow words with specific meanings to take on additional, related meanings (e.g., Glucksberg & Keysar, 1990; Lakoff, 1987; Lehrer, 1990; Miller, 1979; Murphy, 1996). We suggest that mappings that focus on relational structures are more likely to generate stable abstractions than mappings that focus on object attributes. In sum, conventionalization of relational meanings may fulfill an important cognitive function in creating new abstractions.

Is Competitive Learning an Adequate Account of Free Classification?

Jan Zwickel (jzwickel@ix.urz.uni-hd.de)

Abstract

Rumelhart & Zipser's (1986) competitive learning algorithm is an account of unsupervised learning and, as such, might be considered a potential model of free classification behavior in humans. However, selective learning effects (e.g. Dickinson, Shanks & Evenden, 1984) suggest that human learning, at least under conditions of feedback, may be better characterized by an error-correcting system. An experiment is reported that provides preliminary evidence for the existence of a selective learning effect in free classification. Simulations indicate that Rumelhart & Zipser's algorithm does not provide an adequate account of the behavior observed, whilst an error-correcting variant of competitive learning does.

Introduction

Free classification, or free sorting as it is also called, is a procedure in which human participants are presented with a set of stimuli and are asked to group them in any way that seems sensible or reasonable to them (e.g. Bersted, Brown & Evans, 1969; Regehr & Brooks, 1995; Wills & McLaren, 1998). It may be contrasted with the more standard experimental task of category learning via trial-specific feedback that has been the dominant mode of enquiry into humans' categorization abilities for the last fifty years (e.g. Bruner, Goodnow & Austin, 1956; Medin & Schaffer, 1978; Wills, Reimers, Stewart, Suret & McLaren, 2000).

The study of categorization under conditions where each decision receives immediate feedback from a totally reliable source has allowed psychologists great control over the structure of the categories participants acquire. As a methodology, it has been successful in broadening our understanding of the category learning process. However, the level of feedback available in such tasks seems higher than that available in many real-world situations, begging the question of whether what we have learned about the categorization process will generalize to situations where the feedback is absent or scarce.

An interesting parallel may be drawn with the sort of connectionist systems that have been proposed for learning in the presence or absence of feedback. For

example, Rumelhart & Zipser's (1986) competitive learning model is an unsupervised system. It extracts statistical regularities in the input to form categorical representations, and does so in the absence of feedback. In contrast, McClelland & Rumelhart's (1985) model is a supervised system. It can be taught multiple categories (cat vs. dog vs. bagel in their example) but learns to categorize because each stimulus is accompanied by an externally-provided category label.

One of the differences between these two models is the nature of the weight-update algorithms they employ. McClelland & Rumelhart (1985) employ an error-correcting algorithm, where the size of the weight change is proportional to the mismatch between an external teaching signal and internal inputs. In other words, learning only occurs when the system fails to fully predict the teaching signal. Specifically,

$$\Delta w_{ij} = \eta(e_i - i_i)a_j \quad 1$$

where Δw_{ij} is the change in the strength of the connection from unit j to unit i , e_i is the external teaching signal to unit i , a_j is the activity of unit j , and i_i is the total internal input to unit i , this being calculated as

$$i_i = \sum_j a_j w_{ij} \quad 2$$

In contrast, Rumelhart & Zipser's algorithm does not employ error-correction in this sense. Rumelhart & Zipser use the internal input to determine which unit is the "winner" and then change weights to the winning unit by an amount proportional to the difference between the current weight of that connection and an asymptote¹. Specifically, the change in weight from unit j to the winning unit is

¹ Rumelhart & Zipser (1986) also discuss a variant where connections to the losing unit are also changed via Equation 3, but with a much lower learning rate. The current article concentrates on the "winner-only" version, although the conclusions drawn are valid for both variants.

$$\Delta w_j = \eta \left(\frac{a_j}{n} - w_j \right) \quad 3$$

where n is the number of active input units, and the winning unit is the one with the highest internal input. It is assumed in the current paper that active input units have an activity of 1 and inactive input units have an activity of zero.

Error-correction is assumed by some investigators to be a fundamental aspect of human learning in the presence of feedback, as evidenced by the phenomenon of selective learning (see below). If human learning in a free classification task fails to show evidence of selective learning, concerns would arise as to the generality of an empirical research program heavily based on learning with feedback. On the other hand, if selective learning is found to occur in free classification, the sort of unsupervised system proposed by Rumelhart & Zipser may not be an appropriate model for free classification behavior.

Selective learning

Probably the best-known example of selective learning is Kamin's (1969) "blocking" effect. Kamin's study involved rats but, as will be discussed later, there is now abundant evidence that corresponding effects can also be found in human learning (with feedback).

Kamin taught hungry rats that pressing a lever would result in food. Following this, pressing the same lever whilst a noise was present resulted in a mild electric shock. Unsurprisingly, rats learned to not press the lever whilst the noise was present.

Next, the auditory tone was accompanied by a light and pressing the lever whilst this tone-light compound was present also resulted in mild shock. The rats learned not to press the lever whilst the tone-light compound was present.

Group	Stage One	Stage Two	Test
Expt.	N→Shock	LN→Shock	L
Ctrl.		LN→Shock	L

Figure 1: Kamin's (1969) blocking experiment. "N" is an auditory stimulus and "L" is a visual stimulus.

In the test phase, just the light was presented, and the rats' behavior observed. The rats in the experimental condition pressed the lever quite a lot, whilst control rats (which had participated in stage two but not stage one) pressed the lever very little indeed. The design of this experiment is summarized in Figure 1.

The rats in the experimental group appear not to have learned the relationship between light and shock even though the control rats, which received an equal amount

of training with the light-noise compound, have learned the relationship. Why might this be?

A number of animal learning theorists (e.g. Mackintosh, 1975; Pearce & Hall, 1980; Rescorla & Wagner, 1972) have essentially argued that it happens because learning is driven by surprise. For the rats in the experimental group, the shock is not a particularly surprising event because it is predicted by the noise. The rats therefore don't bother to learn about the light in stage two. Similar effects have been demonstrated with undergraduates using computer-based tasks, including simple computer games (e.g. Dickinson, Shanks & Evenden, 1984), stock market simulations (e.g. Chapman & Robbins, 1990) and simulated medical diagnosis tasks (e.g. Gluck & Bower, 1988).

As Rescorla and Wagner (1972) noted, the notion of surprise-driven learning is well-captured by an error-correcting learning rule such as the one given in Equations 1 and 2. In fact, the learning theory they proposed is basically a variant of this learning rule.

An error-correcting system reproduces the blocking effect in the following way. For simplicity, consider that there are three units - the noise unit, the light unit and the shock unit. The external input produced by the presence of a stimulus is 1, and the external input produced by its absence is zero.

Initially, shock is not expected, so the link between noise and shock, and light and shock, are small. During stage one of the experiment, the strength of the link between noise and shock increases and eventually reaches 1. In the second stage, noise, light and shock are all present. However, the internal input to the shock unit is already 1 because of the strength of the link between the noise and the shock. Therefore, no weight change can occur via Equation 1. The light does not become associated with shock, even though it clearly would in the control condition. Under the non-error-correcting algorithm given in Equation 3, the light→shock association would reach an equivalent level in both conditions.

Experiment

It is reasonably clear from previous research that humans and other animals engage in selective learning under conditions of trial-specific, informative feedback. Do humans also display selective learning in a task without such feedback? The experiment reported in this paper represents a first attempt to address this question.

In our experiment, participants had to make up their own categories, although they were constrained by the fact they were only allowed two groups. Previous research demonstrates that category learning can proceed successfully in the absence of feedback (e.g. Homa & Cultice, 1984; Wills & McLaren, 1998).

Our participants received intermittent, non-trial-specific, feedback about their overall level of performance following every 24 stimuli, in order to maintain motivation and encourage adoption of the experimenter-defined categories. We believe that such a procedure is still properly described as "free classification" as no single response can be considered correct or incorrect. Situations where all forms of feedback are entirely absent are probably almost as rare outside the laboratory as situations where feedback is always immediate and trial-specific.

Abstract, novel stimuli were employed in this experiment as we wished to study category learning with adult participants - with such participants the category learning process is probably complete or far-advanced for most realistic stimuli.

Stimulus presentation was brief and followed by a mid-gray mask. The time available for a decision was also very limited. Both of these procedures were employed to encourage participants to rely on relatively non-analytic, similarity-based categorization processes, rather than analytic, rule-based processes.

The basic design of the experiment is shown in Figure 2. The letters A to J each represent sets of features present in the stimuli shown to participants.

In the first phase of the experiment, participants were presented with examples from two different categories. Examples from category 1 were created from a base pattern that contained feature sets G and H. Examples from category 2 were created from a base pattern that contained feature sets I and J. Note that the labels "category 1" and "category 2" are essentially arbitrary in a free classification task - they could be reversed without changing anything in the design or execution of the experiment.

As Figure 2 illustrates, once the participant had mastered the GH vs. IJ categorization they were transferred to a second categorization. Participants proceeded through all five categorizations in this way, at which point the experiment was over.

The datum of central importance in this design is the category to which the first stimulus presented in phase five is allocated. The first stimulus is chosen because subsequent decisions in phase five may be contaminated by learning on previous phase five trials.

Phase	1	2	3	4	5
Cat. 1	GH	GE	AB	AE	CE
Cat. 2	IJ	IF	CD	CF	AF

Figure 2: Design of the experiment. Letters represent sets of features, hence category 2 in phase 3 contains feature sets C and D.

The Rumelhart & Zipser system provides the null hypothesis for this experiment because it predicts that

either key is equally likely to be used. It is perhaps not immediately apparent why this should be. To elucidate, one first needs to note that in each of the first four phases, all features are equally predictive of category membership. This means that, for a system such as Rumelhart & Zipser, in each phase learning should end with two features (A and E in phase four) being equally associated to one category representation, and two features (C and F in phase four) being equally associated to the other category representation. Hence, the first stimulus presented in phase five will activate both category representations equally and so the choice of which category to place it into must be arbitrary. This conclusion is confirmed by simulation in a later section.

Why might one expect anything other than a null result with this design? One possible reason would be if people exhibited selective learning in free classification. Note that, across phases 1 to 4, E and F only occur in situations where the information they provide is partially redundant. In phase 2 the stimuli can be categorized on the basis of whether they contain G or I features, a categorization already learned in phase one. In phase four, the stimuli can be categorized on the basis of whether they contain A or C features, a categorization already learned in phase three. Hence, through analogy to selective learning effects in tasks with feedback, one might consider that E and F develop little control over responding.

Method

Due to space limitations, we are unable to report the pilot studies performed. Reports may be found in McCooe(2000) and Zwickel (2001).

Participants and apparatus

Sixteen first-year Psychology students from the University of Exeter participated to fulfil a course requirement. Participants were tested in groups in a quiet computer room. Stimulus presentation was on 17" color monitors connected to Tiny Pentium III PCs running the DMDX software package (Forster & Forster, 2000, version 2). Responses were collected via the left and right CTRL keys on standard PC keyboards. Participants sat approximately 50cm from the screen.

Stimuli

Each stimulus was made up of 12 small pictures (hereafter "elements") taken from a set of 72 that have been used in a number of previous experiments (see Jones, Wills & McLaren, 1998 for the full set). For any given stimulus, the 12 elements were randomly arranged in a square of 3 rows with 4 icons in each row, and were surrounded by a gray rectangle outline 5.5cm in height and 4cm in width. Figure 3 shows an example

stimulus. Throughout all five phases, no stimulus contained more than one copy of any given element.

Figure 3: An example stimulus

Each of the letters A to J in Figure 2 represent a set of six elements. The assignment of elements to letters was randomly determined for each of 8 pairs of participants, with the remaining 12 elements (72 elements - 10 letter sets x 6 elements per set) being used for practice trials.

In order to control for possible effects of differential salience of the elements, one participant in each pair received the stimuli described in Figure 2 whilst the other received a design where E was transposed with A, and F was transposed with C. Hence, the putatively redundant elements were E and F for one member of the participant pair, whilst they were A and C for the other member. This means that any preference revealed in phase five cannot be due to A and C elements being more salient overall than E and F elements. To aid clarity, all participant data is reported as if E and F were the putatively redundant elements.

The stimuli actually presented to participants were generated by random distortion of the base patterns described in Figure 2. Each element in a base pattern was given a 10% chance of being replaced by a randomly selected element from the other base pattern (no element occurred more than once in any given stimulus).

An example may be helpful. To create an AF stimulus in phase five, the six A elements and the six F elements were randomly arranged in the four-by-three grid of the stimulus. Each element was then given a 10% chance of being replaced by a randomly selected element from set C or E. This method of stimulus construction produces training examples which are composed predominately of elements characteristic of a particular category but which also exhibit considerable variability.

Procedure

The five phases described in Figure 2 were preceded by some general written instructions and a brief practice phase to familiarize participants with the procedure. The experiment then proceeded in blocks of 24 trials.

On each trial, a stimulus was presented for 800ms and followed by a mid-gray mask that was presented for 1200ms. If a response was not detected within 2000ms of stimulus onset, the trial terminated with the message "You responded too slowly, please speed up!" and the participant was moved on to the next trial.

Each block comprised the sequential presentation of 24 stimuli, 12 from each of the two categories. At the end of each block a short message appeared stating the percentage of correct responses made by the participant in that block, and that they needed to score more than 80% to proceed to the next part of the experiment.

Clearly, percent correct has a slightly different interpretation in a free classification task to a task with trial-specific feedback as the relationship between categories 1 and 2 and the two response keys is arbitrary. Hence, percent correct was computed under the assumption that category 1 would receive a particular response, and the resulting number was subtracted from 100 if it was less than 50.

When a participant's score exceeded 80% they were moved on to the next phase of the experiment, after having been presented with the message "You did very well! You are now entering the next phase". If participants completed 10 blocks without ever reaching the 80% criterion they were moved on to the next phase with the message "You are entering the next phase as you have been in the last block of this phase".

Results

Consider Figure 2 again. The central null hypothesis we are attempting to reject is that, in the first trial of phase five, a participant will be no more likely to categorize AF using the response typically made to AE in phase four than the response typically made to CF in phase four. Similarly, they will be no more likely to categorize CE using their typical AE response than their typical CF response.

Of the 16 participants tested, 12 used the same response key for CE that they had typically used for CF (or the AE response key for an AF stimulus). Three participants showed the opposite response, using the CF key for an AF stimulus or the AE key for a CE stimulus. The remaining participant could not be described as having a preference for any in key in response to AE or CF as they scored exactly 50% across phase four. Treating this participant in the manner that makes it hardest to reject the null hypothesis, we can state that at least 12 participants emitted the CF→CE (or AE→AF) response, whilst no more than 4 participants emitted the opposite response. Given the null hypothesis would predict 8 responses of each type, the probability of the null hypothesis being correct is smaller than 0.05, $\chi^2(1) = 4.0$. The effect is also significant with an exact binomial test.

Participants completed a mean of 5.88 blocks in phase one, 4.13 blocks in phase two, 6.12 blocks in phase three, 5.75 blocks in phase four, and 5.56 blocks in phase five. The number of participants failing to achieve more than 80% correct in the five phases were 6, 3, 7, 7 and 7 respectively.

Discussion

The results of the current experiment appear to be problematic for those that would attempt to explain free classification behavior in terms of the competitive learning algorithm of Rumelhart & Zipser (1986). The model predicts no preference for which of the two categories developed in phase four are used to categorize the first stimulus in phase five, yet a clear preference was observed. The direction of the preference is that predicted if one assumes the presence of selective learning in free classification.

One possible defense of the Rumelhart & Zipser algorithm is that its predictions were derived for a situation where learning in each phase is essentially complete before the next phase begins. Given the relatively high numbers of participants failing to reach criterion, it might reasonably be argued that asymptotic predictions are not appropriate. Does this make a difference? This is one of the questions addressed in the following section.

Modeling

We employed simulation techniques to more thoroughly investigate whether Rumelhart & Zipser's (1986) competitive learning algorithm could accurately reproduce the categorization preference observed in our experiment. To this end we set up a network with 72 input units (one for each element) and 2 output units (one for each category). Each input unit had a forward connection to each output unit, and the connection weights were initialized to small, random values.

One network simulation was performed for each participant in the experiment, with weights being initialized for each participant. The nature of the stimuli presented to a simulated participant, and the order in which they were presented, were determined by the specific stimuli presented to a corresponding human participant. After the presentation of each stimulus, the winning category node was determined in the same manner as Rumelhart & Zipser (1986). In other words, it was determined by calculating the total internal input to each unit, and selecting the unit with the larger total. The weights from each of the input units to the winning category unit were then updated in accordance with Equation 3. The weights of the losing unit remained unchanged.

The value of η (the learning rate) employed by Rumelhart & Zipser was 0.05. At this value, no preference in the categorization response to the first stimulus in phase five was found. Six simulated participants made CF→CE or AF→AE responses whilst six made the opposite response. The nature of the response made by four simulated participants could not be determined because in phase four they employed both category nodes equally for both stimulus types.

Hence, unlike the human participants, the networks did not display a categorization preference in phase five.

The Rumelhart & Zipser (1986) algorithm was applied to our data with a wide range of learning rates (0.001 to 0.009 in steps of 0.001, 0.01 to 0.09 in steps of 0.01, and 0.1 to 0.9 in steps of 0.1). In no case did the algorithm display a categorization preference in phase 5.

An error-correcting competitive algorithm

We also attempted to simulate our result using an algorithm that combined the error-correcting principle of Equations 1 and 2 with the basic properties of the competitive learning algorithm of Equation 3. On any trial, the winning unit was determined in the same manner as the Rumelhart & Zipser model. The weight-update algorithm employed on each connection from an input unit j to the winning unit was

$$\Delta w_j = \eta \frac{(1-i)}{n} \quad 4$$

for connections from active input units and

$$\Delta w_j = -\eta(1-i) \times \frac{n}{m} \quad 5$$

for connections from inactive input units. In these equations, η is the learning rate, i is the total internal input to the winning unit, n is the number of active input units and m is the number of inactive input units. The weights from input units to the losing unit are not changed. This chimera of an algorithm is not equivalent in behavior to either of its components but does preserve some of the properties of each.

Removing the weight update algorithm of Equation 3 from our previous simulation, and replacing it with the algorithm described in Equations 4 and 5, we find a dramatic change in behavior. Now, at a learning rate of 0.05, all 16 simulated participants make CF→CE or AF→AE responses. In other words, the simulation now reproduces the behavior observed in our human participants, although the overall level of learning is slightly higher in our simulation. A reliable preference is found for a wide range of learning rates - from 0.01 to about 0.4.

Conclusion

The experiment reported in this paper provides preliminary evidence that the ubiquity of selective learning effects in tasks with immediate, trial-specific feedback extends to some categorization tasks where feedback is scarce and not trial-specific. To the extent this phenomenon is found to be general to free

classification tasks, it casts some doubt on the adequacy of certain types of competitive learning algorithms as accounts of free classification behavior. In particular, an algorithm suggested by Rumelhart & Zipser (1986) was found to have difficulty in reproducing the results found. We suggest that a competitive algorithm which includes some aspect of error-correction may be a more appropriate account. One simple algorithm of this type was described, tested, and found to be able to reproduce our results.

The two main avenues of future research suggested by the results and simulations in this paper are a) investigation of the generality of selective learning effects in free classification, b) consideration of whether other unsupervised systems (e.g. Adaptive Resonance Theory, Grossberg, 1976) are capable of accounting for the results so far found.

A Formal Analysis of Intelligent Agents with Mathematical Tools

Zippora Arzi-Gonczarowski (zippie@actcom.co.il)

Typographics, Ltd.; 46 Hehalutz Street

Jerusalem 96222, Israel

ISAAC ('Integrated Schema for Affective Artificial Cognition') is a mathematical model of intelligent agents, which gives rise to a formal theory that could be implemented computationally.

Similar to the natural evolutionary context, the schema starts from a simple model of corresponding sensations and reactions. It then structures 'upgrades' (e.g. handle conflicting reactions, internal representation, and so on) on top of that, using generative reasoning to systematically obtain and study the properties of these upgraded structures. Among other things, this approach yields a continuous bridge from low level to high level intelligence.

A *perception* snapshot is structured as a set of *world elements* that constitutes an environment (real or imagined), a set of *connotations* that constitutes a collection of discriminations, and a set of *behaviors*. Behaviors are conjured up on the basis of a *perception predicate* that relates between world elements and their connotations in a three valued manner (*true, false, undefined*). With real environments, that basic schema approximates models of simple forms of intelligence. For higher level forms of intelligence, mind activities (cognitive, behavioral, affective) are modeled as streams of perceptions. Along these streams, all the components mentioned above could adapt dynamically: be modified, extended, merged, and so on. In mathematical terminology, perceptions are *objects*, and passages from one perception to another are modeled as *morphisms*.

In the course of a few years of ongoing research, a variety of mind processes have been modeled on the basis of these uniform, yet flexible, premises, capturing mental activities from streams of interpretations, through behavior development and integration, representation formation, imaginative design and anticipation, analogy making, to social and self perception. Each publication has been appraised as a model of the relevant mind aspect, but as a collection they also feature an additional value of an integrated whole: because they share uniform modeling premises, the various processes can be neatly composed and alternated between, modeling multifaceted intelligences.

Mathematical treatments are naturally expected to come up with equations. The equational re-

sults of ISAAC are categorical commutative diagrams that state where one formalized mind process is a 'paraphrase' of another. These diagrams are like high level 'blue prints' that provide a computational schema with basic structural guidelines for neat agent architectures.

Mathematization has, indeed, proven a powerful modeling tool for other scientific domains. In cognitive science, however, the open ended diversity of phenomena that need to be modeled has made it difficult to capture things in a uniform manner. If one were to overcome that obstacle, then this would probably be by finding a suitable level of abstraction: high enough to absorb a variety of phenomena, but not too high so that meaningful things could still be stated. Mathematical categorization is a tool that has been developed precisely for such purposes within mathematics itself. ISAAC deploys well developed category theoretical tools for cognitive science purposes, yielding a general, yet rigorous, schema.

Pre-theoretically, ISAAC is grounded by intuitions. As a theory, the treatment proceeds as if the semantic primitives were context independent: All definitions, constructions and results are tidily operated within the abstract mathematical framework. Then, they are invariably examined with regard to the grounding intuitions, pre-theoretical conceptions, and existing knowledge about the modeled processes. Results that have not been anticipated at the outset provide supporting arguments that the proposal is apparently on a promising track.

Substitution instances of the schema could be applied to describe, or to design, particular agents, filling in detailed domain-specific features to approximate particular agents. The foundational schema avoids over determinism and captures abstracted structures and mechanisms that are shared by intelligent agents. This yields a unifying theory and, hopefully, contributes to:

- (1) Cognitive science becoming a science, and to
- (2) Integrative artificial intelligence that does not lose the big picture by over fragmentation.

Distinct Errors Arising From a Single Misconception

Ryan S. Baker (rsbaker@cmu.edu)

Albert T. Corbett (corbett@cmu.edu)

Kenneth R. Koedinger (koedinger@cmu.edu)

Human-Computer Interaction Institute, Carnegie Mellon University
5000 Forbes Ave., Pittsburgh, PA 15213 USA

Data and Introduction

We present an account of the mistakes students have been observed to make when generating scatterplots, and give evidence that somewhat disparate error behaviors can be traced to the same strategic decision.

In two prior studies (Baker, Corbett, & Koedinger 2001, 2002), we observed middle-school students attempting to generate scatterplots (which have a quantitative variable on each axis) but making two conceptually similar errors. When given both categorical and quantitative variables but no advice on which to place in their graph, 15% made what we call the *choice* error, incorrectly choosing a categorical variable for the X -- 0% used the correct variables. Naming the variables to use in the question did not eliminate this error, but 77% used the correct variables. 13% of those students, however, then made what we term the *representation* error: treating the values of the quantitative X variable as if they were categorical. They wrote the variable's values along the axis in the order they appeared in the data table, rather than numerical order, e.g., placing "22 20 23 25 24 19 23" along the axis rather than "19 20 21 22 23 24 25". Labeling the axis variables for the student did not significantly reduce the representation error's frequency.

Our conjecture was that students made both errors due to a substantially greater familiarity with bar graphs, leading to the belief that graphs always have a categorical x-axis. A possible alternate conjecture for the representation error is that students don't understand the difference between categorical and quantitative variables. However, this conflicts with their comparatively greater ability to represent the Y axis quantitatively, as is done in a bar graph.

Modeling

In drawing each axis of a scatterplot, there are two key decisions for the student to make -- which variable to graph and how to represent its values. We developed an ACT-R (Lebiere & Anderson, 1998) model of these decisions and fit it to the students' behavior displayed in Table 1. In alternate fits we modeled the two correct decisions (correct variable choice and quantitative value representation) as two different productions (if-then rules) or the same production. Similarly, we modeled the two errors (categorical variable choice and categorical representation of a quantitative variable) as two productions or the same production. Modeling the two correct decisions as different productions produces a significantly better fit than modeling them as a

single production ($F(1,30)=39.853$, $p<0.001$). The model where the two errors stem from the same strategic production has equal fit but superior parsimony to the model where they stem from different strategic productions. ($BiC(same)=77.00$, $BiC(different)=79.28$) The former model achieves an excellent fit to the overall pattern of data from the two experiments. ($r=0.990$, mean absolute dev = .057)

This model is generally consistent with but clarifies our early conjectures. As shown in the top row of the table, students never pick a quantitative variable for the x-axis unless one is suggested. This implies that in these studies correct selection of a quantitative variable just reflects the ability to follow directions; treating a quantitative variable as quantitative, on the other hand, is modeled as active knowledge of the difference between quantitative and categorical variables. The two errors in this account, selecting a categorical variable and treating a quantitative variable as categorical, reflect a single misconception. These students know the difference between categorical and quantitative variables, but are biased to make the X axis categorical in any way possible, consistent with their prior experience with bar graphs.

Thus, in this domain multiple error behaviors arise from a single misconception, an overgeneralization of their prior knowledge of bar graphs.

Table 1: Percent occurrence of behaviors

	No prompts	No labels	X label	Y label	Both label
Correct	0	53	59	62	61
Choice error	15	27	9	27	8
Rep error, X axis only	0	10	14	12	10
Rep error, Y axis only	0	0	0	0	0
Rep error, both axes	0	3	4	0	6
Other/ Give Up	85	7	14	0	15

Belief in the Hot Hand Improves Performance: A Mathematical Model

Bruce D. Burns (burnsbr@msu.edu)

Department of Psychology, Michigan State University
East Lansing, MI 48824-1117

The widely held belief in the "hot hand" in basketball suggests that a player experiencing a streak should be given the next shot. However Gilovich, Vallone & Tversky (1985) found that streaks of hits in basketball shooting were no more likely than chance, so basketball shots are independent events. Thus it has been widely accepted that belief in the hot hand is a fallacy. Starting with the question of what are the goals of basketball players, Burns (2001) argued that the data only demonstrated that the hot hand is invalid as an individual cue to when a player will hit a shot, not that it is an invalid allocation cue for deciding who to give the next shot to. Streaks should occur more often for good shooters.

Burns (2001) used computer simulations to show that giving the next shot to players who hit their last shot improved a basketball team's scoring. However these simulations had two weaknesses. First, occasionally the simulations utilizing the hot hand did not outperform those not using it. Although less than 1% of the simulations, they raised questions about the claim that belief in the hot hand would always be expected to help. Second, in order to limit the number of free parameters and make the entire parameter space explorable, some simplifying assumptions had to be made. Although it was possible to argue that these assumptions were not critical, it would be better to demonstrate this directly.

A Markov Model

To address concerns about the simulations I constructed a Markov model of the first two shots in basketball. The first two shots were modeled because at least one shot is necessary before there can be a hot hand, and if scoring is improved in the first two shots it should be improved over any number of shots. My analysis does not however assume that the hot hand is defined by just one hit. The model could be applied to any definition of the hot hand in which it represents a temporary elevation in the probability of giving a player the next shot that is triggered by recent success.

The model has four parameters and represents Player X and Player (or Players) Y. A bias parameter b represents the probability of giving the next shot to Player X, whereas the same probability for Player Y is $1-b$. The bias parameter represents any bias to give the ball to a player (e.g., high shooting percentage, perceived ability, friendship, etc) that is independent of recent success. The model does not incorporate a parameter for belief in a "cold" hand because there is no empirical evidence for this belief.

The model has separate parameters for the shooting percentages for the two players, s_x and s_y for Players X and Y respectively. The hot hand parameter h temporarily

elevates the probability of a player being given the next shot after a hit. Thus the probability of Player X being given the next shot after a hit is $b + h(1 - b)$. All parameters have a range of 0.0 to 1.0. The expected number of hits after two shots, calculated by summing the expected outcomes of all 16 possible states is:

$$E(\text{hits after two shots}) = 2(b(s_x - s_y) + s_y) + h(b - b^2)(s_x - s_y)^2$$

The $h(b - b^2)(s_x - s_y)^2$ component is never negative, thus belief in the hot hand can never lower the expected number of hits. Any positive value of h will raise the expected outcome so belief in the hot hand increases expected scoring, just as was shown in the simulations. However there are the same two exceptions to this: h will have no effect when $s_x = s_y$ (if there is no difference between players then it does not matter how shots are allocated), and when $b=1$ or $b=0$. This pure strategy of always giving the ball to one player is neither observed (even when it is optimal) nor would be desirable in NBA basketball. Game theory predicts that for most interesting competitive games there is a mixed strategy equilibrium.

Conclusions

This Markov model provides a mathematical proof that belief in the hot hand is beneficial if shots are independent events. In this way it expands on Burns' (2001) simulations. It also makes clear that giving the ball to good shooters and to players experiencing the hot hand are not mutually exclusive strategies. Instead allocating shots between players is a multi-cue decision making task in which both players' base-rates of success over the long term and short-term streaks are valid allocation cues. Giving weight to both of these allocation cues will improve the amount that a team will be expected to score. False beliefs that shots are dependent may be a way to maintain utilization of streaks.

In this paper we investigate the human reasoning applied to the mathematical problem-resolution process. Our approach is based on two main settings: *a.* the investigation of mental processes involved in the human reasoning applied to problem resolution; *b.* the analysis of differences in the categorization and resolution of mathematical problems by novices and experts.

In *a.* we sought to contribute for the rupture of the logical-formal reasoning paradigm. In fact, we sought to contribute for the rupture of the idea that identifies the human as a completely rational entity, which invokes a thinking way that adheres the rules of an explicit form. Our results show that the human reasoning is not determined exclusively by logical-formal guidelines, but is rather determined by characteristics and pragmatics aspects of the context.

In *b.* we sought to analyze more effectively the problem-resolution process. We concentrated our discussion on the differences in the categorization and resolution of mathematical problems by novices and experts. Our results indicate for a problem categorization and subsequent resolution: experts are guided by organized logical principles, and novices are guided by superficial elements found in its enunciation.

The Role of Logical Structure and Premise Believability in Belief Revision

Dustin P. Calvillo (calvillo@psych.ucsb.edu)

Department of Psychology, University of California
Santa Barbara, CA 93106-9660 USA

Russell Revlin (revlin@psych.ucsb.edu)

Department of Psychology, University of California
Santa Barbara, CA 93106-9660 USA

Belief Revision

Belief revision occurs when one moves from one belief state to another after encountering some data that are inconsistent with one's initial belief set. Experiments in belief revision have demonstrated that the initial logical structure of an argument affects how reasoners revise their beliefs. When arguments for changing beliefs are made in a logical form, the typical finding is that the major premise is revised more frequently than the minor premise. This is evident when the modus ponens (MP) inference is contradicted (if p then q; p; therefore, q), while there is no clear preference when the modus tollens (MT) inference is contradicted (if p then q; not q; therefore, not p) (Dieussaert, Schaeken, De Neys, & d'Ydewalle, 2000; Elio & Pelletier, 1997; Politzer & Carles, 2001). Others have reported a different finding: reasoners revise belief in the major and minor premises equally often in MP problems, but prefer to disbelieve the minor premise in MT problems (Revlin & Calvillo, 2002; Revlin, Cate, & Rouss, 2001). In three experiments, we explore possible explanations for these two different patterns of results.

Three possible explanations for the inconsistent results are the types of major premises, the revision alternatives presented to participants, and the prior believability of the major premises. The major premises used by Elio and Pelletier (1997), Dieussaert et al. (2000), and Politzer and Carles (2001) were conditional (if p then q) and somewhat neutral in believability. Participants in these experiments were allowed to express uncertainty toward premises. The major premises used by Revlin et al. (2001) and Revlin and Calvillo (2002) were universal quantifiers (all p are q) and considerably more believable. Participants in these experiments were forced to decide, with certainty, to disbelieve the major or minor premise.

In Experiment 1, we assigned 80 introductory psychology students from the University of California, Santa Barbara into four groups. Logical structure (MP or MT) and type of major premise (conditional or quantifier) were between-participants variables. The major premise revision rates are presented in Table 1. The rates for both quantifiers and conditionals were similar to those found by Revlin et al. (2001). Logical structure had a significant effect, type of major premise did not, and the two variables did not interact. This ruled out the use of different major premise types as an explanation for the different previous findings.

In Experiment 2, we assigned 50 participants to two groups and presented them with MP and MT problems like

in Experiment 1, but gave them the revision alternatives used by Politzer and Carles (2001). As seen in Table 1, logical structure had a reliable effect on revision rates and the major premise revision rates were similar to those of Revlin et al. (2001), ruling out the use of different revision alternatives as an explanation for the inconsistent results.

Table 1: Major premise revision rates by logical structure.

	MP	MT
Experiment 1: Conditional	0.329	0.044
Experiment 1: Quantifier	0.263	0.107
Experiment 2	0.465	0.123
Experiment 3: Low believability	0.751	0.701

In Experiments 1 and 2, the major premises used were highly believable. In Experiment 3, we gave 47 participants either MP or MT problems with major premises of low-believability. The results, as seen in Table 1, were similar to those of Elio and Pelletier (1997). There was a preference to revise belief in the major premise in both MP and MT problems and there was no effect of logical structure.

Experiments 1 and 2 ruled out the use of different types of major premises and revision alternatives explanations for the varying results in the literature. Experiment 3 showed that believability of the major premise is a likely source of the different patterns of results, demonstrating the need for models of belief revision to include initial premise believability to account for how reasoners revise beliefs.

Displacement affects duration estimation, but not the other way around.

Daniel J. Casasanto (djc@mit.edu)

Lera Boroditsky (lera@mit.edu)

Department of Brain and Cognitive Sciences, Massachusetts Institute of Technology
77 Massachusetts Avenue NE20-423 Cambridge, MA 02139 USA

Introduction

How do we mentally represent and reason about domains for which little sensory information is available? One suggestion is that our understanding of abstract domains is intimately dependent on our understanding of richer, more experience-based domains (Boroditsky, 2000, 2001; Gentner et al., 2001; Gibbs, 1994; Holyoak & Thagard, 1995; Lakoff & Johnson, 1980, 1999). For example, people's understanding of time appears to be dependent on spatial knowledge (Boroditsky, 2000; Boroditsky & Ramscar, 2002). Previous evidence suggests that there is an asymmetric relationship between the domains of space and time. Whereas spatial knowledge was found to be useful for reasoning about time, temporal knowledge did not facilitate spatial reasoning (Boroditsky, 2000).

The present studies investigate whether this asymmetric relationship between space and time holds even for low-level representations of the two domains.

In a series of simple psychophysical tasks, participants viewed a moving stimulus and estimated either its displacement or its duration. Results show that temporal estimates were strongly modulated by the displacement of the moving stimulus, even when participants were encouraged to attend selectively to temporal information. In contrast, spatial estimates were not modulated by the duration of the moving stimulus when instructions encouraged selective attention to spatial information. Spatial estimates were only weakly correlated with stimulus duration when participants were required to attend to both temporal and spatial information simultaneously.

Experiment 1

Methods

Moving lines were presented on a CRT monitor. Line durations and displacements were varied parametrically. Durations ranged from 1 to 5 seconds in 0.5 second increments. Displacements ranged from 200 to 800 pixels, in 75 pixel increments. Nine durations were fully crossed with nine displacements to produce 81 distinct lines. Lines 'grew' horizontally across the screen one pixel at a time, from right to left, at rates ranging from 40 pixels/second to 800 pixels/second. Each line remained on the screen until its maximum displacement was reached.

Participants viewed 162 moving lines, one line at a time. Immediately after each line event, a prompt appeared indicating that the participant should reproduce either its duration or its displacement by clicking the mouse to indicate

the beginning and end of the estimated temporal or spatial interval.

Results

Participants' temporal and spatial estimates were highly accurate. Target duration correlated positively with estimated duration ($r^2=0.96$), and target displacement correlated positively with estimated displacement ($r^2=0.97$). The effect of target displacement on estimated duration ($r^2=0.72$) was greater than the effect of target duration on estimated displacement ($r^2=0.36$).

Experiment 2

Methods

Materials and design were exactly as described in Experiment 1. The procedure was identical with the following exception: in Experiment 2, participants were notified before each trial whether they would need to reproduce the duration or displacement of the moving line.

Results

Again, participants' temporal and spatial estimates were highly accurate. Target duration correlated positively with estimated duration ($r^2=0.96$), and target displacement correlated positively with estimated displacement ($r^2=0.99$). The effect of target displacement on estimated duration ($r^2=0.82$) was much greater than the effect of target duration on estimated displacement ($r^2=0.01$).

Evaluating Information Design for Notification Systems

C. M. Chewar (cchewar@cs.vt.edu)

D. Scott McCrickard (mccricks@cs.vt.edu)

Department of Computer Science, Virginia Polytechnic Institute and State University
Blacksburg, VA 24061-0106 USA

As computing platforms continuously grow in processing power, diminish in size, and are creatively integrated into every facet of the human experience, popular demand also increases for unfettered access to information of interest, necessitating insightful design for a variety of displays. While engaged in their daily discourse, occupied with activities such as driving, desktop computing, or interacting with others, people often want to remain notified about news items, collaborative efforts, and other changing information. Decision requirements within new settings or situations may prompt immediate interest in accessing related data. Notification systems in the form of ubiquitous computing devices, to include wearable computers, vehicle information systems, and handheld devices, are relied on support these information needs. Desktop computer users also depend on small-sized secondary display applications to provide similar notification information.

However, information conveyed through these devices and applications is often perceived with short, discrete attention shifts and glances rather than longer periods of full attention perception that has been considered typical of human-computer interaction. Certainly, this paradigm has implications for information design, rooted in cognitive processing and human attention limitations. Adding to this challenge, user goals are difficult to predict and often conflicting. For example, users may not want to be interrupted from a primary task, although they still wish to maintain awareness of information over a period of time or recognize specific information states. In other usage scenarios, users may wish to be alerted about information and attracted to some interaction. Platform capabilities may also mandate minimalist information representation, presenting an imperative for reevaluation of design guidelines for a wide array of emerging computer interfaces within these constraints.

Objectives and Related Work

Through empirical study, we seek to understand how various options for information encoding and design, presented within a dual-task situation, simultaneously affect user interruption while enabling reaction and comprehension of notifications. Although much work has been done to understand relative effectiveness and expressiveness of visual primitives within the human-computer interaction field, there are few empirically established design guidelines available for digital displays that are typically not a user's main attention focus. Cleveland and McGill's ordering of graph attributes provides guidance for primary task displays (1984), and

Cleveland has extended consideration of graphical attribute effectiveness to specific information extraction tasks (1994).

However, the dual-task nature of notification systems usage requires evaluation of many other system variables for strong empirical study validity. For example, various combinations of mental and physical workload levels, cross-modal or intramodal presentation of the two tasks, and competing demand for sensory channels and short-term memory (Wickens & Hollands, 2000) will certainly have implications for fulfilling objective information design requirements. Empirical methods allowing reliable replication, measurement, and modeling of these variables are pivotal for creating notification systems guidelines.

Continuing Work

Initial findings from our work show that Cleveland and McGill's guidelines for use of visual attributes do not hold for dual-task situations where a distraction to a primary task requiring high attention and manual interaction must be minimized (Tessendorf et al., 2002). Additionally, we have seen evidence that information design for decision-support notification systems is best accomplished with cross-modal representations as a primary task's visual sensory demand level increases (tasks tested within a CAVETM virtual environment and on a desktop computer). Continuing studies will lead to development of regression models and tables, supporting rule-based presentation adaptivity, complementary to efforts such as Horvitz's PRIORITIES system, which makes inferences about a user's attention state and calculates expected cost of an interruption to determine the most suitable presentation method (Horvitz, Jacobs & Hovel, 1999).

The Recognition of Overlapped Chinese Characters at Two Spatial Scales

Yu-Ju Chou (sallyc@cogsci.ed.ac.uk)

Richard Shillcock (rcs@cogsci.ed.ac.uk)

Division of Informatics, University of Edinburgh,
2 Buccleuch Place, Edinburgh, EH8 9LW UK

Introduction

The two hemispheres may have different strategies allowing various perceptions to be processed independently, such as near and far, ambient and focal, and low-level subcortical communications, contrasted to high-level cognition. Then what happen when the ambient processing of the large character, and the focal processing of small characters are merged? This study hypothesized that two repeated items should facilitate the recognition. Additionally, large stimulus captures visual attention, which should speed up the recognition of large characters, compared to small characters, and because this was a preattentive factor, the effect should not have a gender difference.

Experiment

Thirty-two Chinese characters, half high frequency and half low frequency, were presented in three versions: Large (400*400, units defined by Psyscope), Small (50*50) and Overlap version. The Overlap version was a large character overlapped by a small identical character in the centre. And the centre was emptied beforehand to make sure that the small character was not obscured by the large one. Characters and versions were arranged by Latin square design. A fixation point was presented in the centre of the monitor for 500 msec, followed by a character lasted for 150 msec, and then followed by a mask picture lasted for 500 msec. Native Chinese speakers, ten males and eleven females, participated in this study. They made a lexical decision by clicking the button on the response box with their index fingers, buttons were counterbalanced between people, and the response times were recorded by Psyscope.

Analysis and results

Frequency effect was significant by subjects and by items ($p < .01$), as High frequency characters were recognized faster than Low frequency characters. Size effect was significant only by subjects ($p < .01$) as Overlapped characters were recognized slower than Large and Small versions. Gender difference was insignificant ($p > .05$). A two-way interaction between Gender and Size was significant in the by-items analysis ($p < .05$). Post hoc tests show that females recognized Overlap characters quicker than Large and Small ones, but no significant difference for males.

Discussion

That large characters were recognized slightly quicker than small characters supports our hypothesis that the visual attention was more likely caught by larger objects, compared to small objects. And as presumed, Gender effect was not significant.

However, there were large characters in the overlapped versions, but the recognition of overlapped version was slowest. This suggests that in the overlapped version the small characters interfered with their recognition, resulting in the delay of the response latency. The degree of interference was greater in females than in males. Males did not show facilitation of recognition in the overlapped condition. It might be reasonable to interpret that in general, females performed more cautiously in doing the recognition task than males. It might be the cognitive style of the sexes that differentiate the results.

Conclusion

The result showed that Overlapped characters lengthened the response latency and seemed to interfere with the recognition process.

Acknowledgments

I am grateful to my supervisor, Dr. Richard Shillcock, for his long-term guidance and supervision.

Introduction

Is phonetic information encoded by distributional biases in the lexicon? Are phonotactic constraints robust enough to help a learner infer the phonic pattern of a language? Our work in progress attempts to shed light on these questions via: (i) statistical description of the distributional biases in phone sequences in a lexical database and (ii) connectionist simulation. The simulation focuses on V-to-V relations in V(C)'C(C)V phone strings since both harmony and contour constraints (the tendency for the vowels to share or avoid repetition of phonic properties, respectively) have been found in the distributional study (Albano, 2002).

Experiment and Current Results

An SRN (Elman, 1995), with a compression layer added between the input and the hidden layers, was trained to predict the next phone in the word. The 3700 penultimate stressed words in the training set were fed to the network phone by phone. The context layer activation was reset after each word. Phones were encoded as 35 orthogonal vectors; so no phonetic information was supplied to the network. The training set consisted of trisyllabic nouns only. Since the focus of the experiment was the intervocalic transitions, testing was performed by presenting the network with 12 non-words [pV'pVpV], thus controlling for the effects of consonants. The hidden unit activations produced for each phone in the test set were then analysed using PCA, averaging for the 5 harmonic and 7 contour non-words (means were tested for significance with ANOVA).

Figure 1: V1 to V2 Transitions according to PCs 4 and 8.

It is possible to identify dimensions in the principal component space which discriminate for Harmony and Contour. Figure 1 depicts the transition between vowels along the dimensions coded by the 4th and 8th principal components. It can be seen that harmonic vowel pairs are not strongly distinguished in any dimension. In contrast, contour vowel pairs differ significantly in both dimensions.

The trajectories associated to transitions in the subspace spawn by the 4th and 8th components (Figure 2) show that the dynamics for harmony is opposite to the one for contour.

Figure 2: Harmony vs. Contour dynamics for PCs 4 and 8. The direction of the V1V2 vectors is opposed for harmonic and contour vowel pairs.

Phonotactics is best described by non-categorical, probabilistic biases, embodied in the lexicon as constraints on lexical forms which are emergent properties of the operation of dynamical systems that shape language behaviour. So, understanding phonotactics depends on adopting a dynamical point of view.

The Roots of Plausibility: The Role of Coherence and Distributional Knowledge in Plausibility Judgements

Louise Connell (louise.connell@ucd.ie)

Mark T. Keane (mark.keane@ucd.ie)

Department of Computer Science, University College Dublin, Belfield, Dublin 4, Ireland

Introduction

Plausibility plays a central role in human cognition, whether one is considering the alibi of a murder suspect in a crime novel, or assessing the answers of a candidate in a job interview. Other studies have mentioned plausibility judgements in the service of other phenomena (e.g. Reder, 1982), but often without being investigated in their own right. This paper presents evidence that plausibility judgements depend on inferential coherence and distributional information. In the first experiment, we show that the type of inference being made affects the plausibility of a sentence pair. The second experiment demonstrates that the distributional properties of the words in a sentence pair directly influence plausibility.

Experiments

Two experiments advance a novel paradigm in which people make plausibility judgements about sentence pairs. These sentence pairs are manipulated to invite different bridging inferences and to control their distributional scores (as determined by the Latent Semantic Analysis model LSA; Landauer & Dumais, 1997).

In Experiment 1, 40 participants were asked to judge the plausibility of sentence pairs on a scale from 0 – 10 that had been manipulated to support causal, attributive or temporal inferences, or not to invite any obvious inferences at all (i.e. unrelated pairs). The distributional information of each pair (the LSA score of the first sentence against the second) was controlled across inference types.

In Experiment 2, we manipulated distributional information across the causal and attributive sentences to look at the action of both factors together. 24 participants saw two versions of each sentence pair per page (see Table 1), one of which had a relatively high LSA score between the sentences (a strong distributional link) and the other of which had a relatively low score (a weak distributional link). Participants were asked to judge the plausibility of each pair as before, but to make certain that any perceived difference in plausibility between the two versions of each sentence pair was reflected in the scores.

Results & Discussion

Experiment 1's results demonstrate that different inference types differentially affect the perceived plausibility of a discourse. The causal pairs were rated the highest in

plausibility ($M=7.8$), followed as predicted by attributive ($M=5.5$), temporal ($M=4.2$) and unrelated ($M=2.0$). An analysis of variance yielded a significant effect of inference type on plausibility scores, $F(3, 472) = 93.683, p < 0.0001$.

Table 1: Sample Experiment 2 sentence pair variants.

Sentence 1	Sentence 2	Inference X Distribution
The pack saw the fox.	The hounds growled.	Causal Strong
	The hounds snarled.	Causal Weak
	The hounds were fierce.	Attributive Strong
	The hounds were vicious.	Attributive Weak

Experiment 2's results show that the distributional information of a sentence pair affects how plausible it is perceived to be. We examined the proportion of times a participant judged either the strong or weak version of a sentence pair to be more plausible. This analysis shows that in both the causal pairs [$M=59.4\%$, $t(10)=4.893$, $p<0.001$] and in the attributive pairs [$M=60.3\%$, $t(11)=3.753$, $p<0.005$], the weak sentence pair was proportionally rated more plausible than the strong pair.

This gives rise to a very interesting explanation of the joint effects of coherence and distributional strength. We suggest that when there is a strong distributional link, there is an expectation that a coherent inference will be found, and this expectation suggests an initial level of plausibility. When the expectation is borne out – by finding a bridging inference for a strong link, or by not finding one for a weak link – then the level of plausibility suggested by the expectation remains unchanged. On the other hand, when the expectation is contradicted – by unexpectedly finding a bridging inference for a weak link, or failing to find one for a strong link – then the level of plausibility rises or falls accordingly. While distributional information plays an essential role in the judgement process, the degree of coherence is what ultimately validates the plausibility level.

Measures of Real Time Assessment to use in Adaptive Augmentation

Martha E. Crosby (crosby@hawaii.edu)

Curtis Ikehara (cikehara@hawaii.edu)

David N. Chin (chin@hawaii.edu)

Department of Information and Computer Sciences, University of Hawaii
1680 East West Rd. POST 317, Honolulu HI 96822

Cognitive capabilities vary considerably due to people's different levels of expertise and aptitude. Also the cognitive capabilities of any one person will vary greatly over time because of stress, fatigue, injuries, attention lapses, and distractions. In order to augment the cognition of any individual, one strategy is to first assess the real-time cognitive capabilities of that individual and then tailor any augmentation to the current cognitive capabilities of the individual.

The first major problem in real-time adaptive augmented cognition is assessing cognitive capabilities of the person instantaneously. A number of sensors have detected a student's physiological states and actions. Riseberg et al. (1998) frustrated highly motivated users of a game interface by degrading mouse performance at irregular intervals. Galvanic skin conductivity, blood volume pressure, and muscle tension were recorded and correlated to frustration and non-frustration states. Ark, Dryer, and Lu (1999) established the feasibility of correlating physiological measurements to emotions. Crosby, Chin and Iding (2001) demonstrated how eye fixations can be used to analyze users' strategies. Other research projects by Crosby, et al. (2001) suggest that a person's pressure on a mouse is also a good candidate for real-time biometrics to predict cognitive load. Identifying emotions is a complex process and it may not always be necessary to know the precise emotion. If other information such as performance data and focus of attention are available, it may be sufficient to only sense changes in the physiological data.

The data collected by our projects include temperature, heart waveform, galvanic skin response and physical pressures applied to a mouse. Sensors are connected to an electrically isolated micro-controller, which converts the analog sensor signals to digital data for processing, by a master computer. The first sensor is on the finger tip to monitor peripheral temperature, the second sensor is attached to the wrist as a reference to body temperature and the third sensor monitors the ambient temperature at a distance of about 5 cm away from the wrist. The sensors are not attached to a substantial thermal mass that would reduce the response rate, and the minimum detectable change of temperature is calculated to be 0.005 C.

The heart waveform is monitored using an infrared reflective light sensor that is mounted on the same elastic band as the fingertip temperature sensor. The change in blood flow

is measured by changes in reflected light at the skin surface where blood flow is apparent. The heart beat rate is extracted by measuring the time between peaks and the relative blood volume change can be determined by integrating the heart waveform over the desired time. When the sensor is pressed against the fingertip, too much force will obstruct blood flow and too little force will produce unreliable data. The sensor also detects the mean reflected light, which is used to determine the optimum amount of pressure to be applied to the sensor.

The experiments performed in our projects show that simple physiological measurements of GSR, heart rate, temperature, and pupil diameter provide information on changes in user's emotional and subjective states while engaged in cognitive tasks. A subject's physiological state and actions can be indicative of their cognitive performance. Physiological data, collected from people as they use computers to form their tasks, might not consistently predict their emotional state. However, results from our experiments suggest that it is possible to provide the computer with information about the users' cognitive state in real time.

Semantic Memory Retrieval During Conditional Reasoning: Every Counterexample Counts

Wim De Neys (Wim.Deneys@psy.kuleuven.ac.be)

Walter Schaeken (Walter.Schaeken@psy.kuleuven.ac.be)

Géry d'Ydewalle (Géry.dYdewalle@psy.kuleuven.ac.be)

Department of Psychology, K.U.Leuven, Tiensestraat 102
B-3000 Leuven, Belgium

Introduction

Reasoning with conditionals involving causal content is known to be affected by retrieval of counterexamples from semantic memory. This study focuses on the characteristics of this search process.

In Markovits' (2000) recent specification of the memory search process, the number of stored counterexamples is important because it determines the probability that at least one can be retrieved. This specification does not address the impact of additional counterexample retrieval. Indeed, the search process is assumed to stop after the successful retrieval of a single counterexample.

The present study tests an alternative specification of the search process. We examine the assumption that the search process does not terminate after the retrieval of a single counterexample and that every retrieved counterexample has an additional impact on the reasoning process. Here, the number of stored counterexamples will be important because it determines the number of counterexamples that can be retrieved and this number would determine the degree to which inferences will be accepted.

Experiment

A generation pretest measured the number of counterexamples (alternative causes or disabling conditions) participants could retrieve for a set of causal conditionals. One month after the pretest, participants were presented a reasoning task with the same conditionals. We looked at participants inference acceptance ratings for each conditional in function of the number of counterexamples they could retrieve for that conditional.

Results showed that every alternative or disabler that can be retrieved has an impact on the inference acceptance. Acceptance of Modus Ponens and Modus Tollens linearly decreased with every additionally retrieved disabler. Likewise, Affirmation of the

Consequent and Denial of the Antecedent acceptance linearly decreased in function of the number of retrieved alternatives.

These graded effects of up to four different numbers of available counterexamples can not be explained if the semantic search process during conditional

Figure 1. Inference acceptance (7-point scale) in function of the number of alternatives (2a) or disablers (2b) participants could retrieve for a conditional.

reasoning would stop after successful retrieval of a single counterexample. This makes it clear that Markovits' (2000) conditional reasoning model needs to be revised.

Categorization of Emergent Processes by Students at Different Levels of Expertise

Randi A. Engle (RAEngle@pitt.edu)

Micheline T. H. Chi (chi@pitt.edu)

Learning Research and Development Center, University of Pittsburgh
3939 O'Hara St., Pittsburgh, PA 15260 USA

Introduction

Chi and Roscoe (2002) proposed that one reason for the persistence of scientific misconceptions is that students classify scientific phenomena into incorrect ontological categories. In particular, Chi (submitted) has hypothesized that many commonly misunderstood science concepts (like evolution and electric current) are emergent processes in which a macro-level phenomena emerges from complex interactions between entities at a micro-level. Rather than correctly categorizing them this way, students are thought to miscategorize them as non-emergent processes in which there is a more direct relationship between the two levels.

To test this hypothesis, we are conducting a study comparing how participants at different levels of expertise categorize science problems across domains, using a card sorting task modeled on Chi, Feltovich & Glaser (1981). The prediction of Chi's theory is that participants with more expertise will be more likely to distinguish emergent from non-emergent problems while those with less expertise will often conflate them. Experts will also be more likely to refer to the 11 features of the emergent schema (e.g., disjointness, parallelism; see Chi, submitted) in defining their categories.

Method

Participants

Participants consisted of 10 undergraduate and 9 doctoral students from the biology, chemistry, or physics departments at a local university. Undergraduates had all completed 1st year courses in biology, chemistry, and physics. Eight were single majors in one of these disciplines and two were double majors in biology and chemistry. Doctoral students were in their third year or above.

Materials

Participants sorted 24 science problems, 8 drawn from each discipline's 1st year course. Within each discipline, half were emergent and half were non-emergent processes.

Procedure

Participants were asked to sort the problems into piles with similar mechanisms for linking the macro and micro levels. In the 1st sort, they were allowed to make as many piles as they wished. In the 2nd sort, they were asked to divide the cards into just two piles. In the 3rd sort, the experimenter sorted the cards into emergent vs. non-emergent processes, and participants were asked to infer the distinction. In all

cases, participants were asked to explain the explanatory mechanism each pile represented and why each problem fit.

Results

As a preliminary measure of the degree to which participants distinguished emergent from non-emergent processes, we calculated a weighted average (by pile size) of the absolute difference between the number of emergent versus non-emergent processes in each pile by the number of cards in the pile. For example, 3 piles—one with 5 emergent & 5 non-emergent problems, a 2nd with 1 emergent & 7 non-emergent problems, and a 3rd with 6 emergent & 0 non-emergent problems—would get a score of $[10(0/10) + 8(6/8) + 6(6/6)] / 24 = 12/24 = .50$. A value of 1 on this score represents perfect separation of emergent versus non-emergent processes while 0 represents perfect 50/50 mixing. Mean separation scores were .58 for doctoral students, .53 for single majors, and .73 for double majors, although none of these differences are statistically reliable.

A complicating factor is that participants sometimes put, for example, only emergent problems in a given pile for reasons unrelated to their emergence. Thus, we analyzed participants' definitions of their categories to determine whether they referred to any of the 11 features of the emergent schema. Doctoral students' categories referred to more emergent features (1.78) than single majors (0.13; $t(9) = 3.08$, $p < .05$). Double majors referred to even more of them (3.50), but more data is needed to see if this is reliable.

Discussion

Doctoral students and double majors used more features of the emergent schema in sorting science problems than single majors, although they were no more likely than single majors to create piles that distinguished emergent and non-emergent processes. In future work, we will include in our sample more double majors as well as professors to further investigate the nature of expertise in emergent processes.

The Autozoetic Hypothesis On Creativity: Memory and Cognition in Pollock s Abstract Art.

Carlos H. Espinel (espinelmd@aol.com)

The Blood Pressure Center, Washington, and Georgetown University Medical Center, Dept. of Medicine
1715 North George Mason Dr., Suite 401, Arlington, VA 22205 USA

Art and Cognitive Science.

Art presents a challenge and an opportunity for study in cognitive science (Espinel, 1994; 1996; 1998). This research concerns the creation of abstract art. One that is supposed to impact the viewer without recognizable, without memory-evoking images (Schapiro, 1980). This ideal was achieved by Jackson Pollock, who with it pioneered modern American art. His paintings, tangles of smears of paint on canvas, have been explained as unconscious expressions (Schapiro, 1980 & O Connor FV, Thaw EV, (Eds.), 1978). An Autozoetic Hypothesis on creativity would suggest otherwise. Here is a study of a painting representative of Pollock s abstracts, *Lavender Mist*, at the National Gallery of Art (Figure 1).

Method.

An investigative approach was devised previously to study works of art (Espinel, 1994; 1996; 1998; 2002). This method is applied to analyze concerning *Lavender Mist*: 1. Reports, Pollock s own and art experts , about his creation; 2. In the painting, by direct observation, photography, and digital techniques devised by the author (Espinel, 2002): a) physical and aesthetic characteristics, and b) systematically, cues of space and form; 3. Other works by Pollock, exhibited and published.

Results.

1. Reports did not disclose memories, thoughts or experiences that might have originated Pollock s creation. 2. In *Lavender Mist*: a) Direct observation and photography showed no recognizable space or form cues (Figure 1); b) Digital analysis by color revealed 9 layers of smears, called here, digital paintings (Figure 2); c) Of these, 8 showed no recognizable space or form; but d) In the ninth, *The Pink*, the image of a horned animal was discovered (Figure 3). 3. In a Pollock drawing from his symbolic stage, 10 years before, an image was found that is reminiscent of the one hidden in *Lavender Mist* (Figure 4).

Conclusions.

1. The discovery of the horned animal image under tangles of smears suggests Pollock s awareness of it, and a conscious, deliberate concealment. 2. That the image can be traced to a past event, to a contextually specific stage of his artistic development, suggests Pollock s autozoetic recall. 3. The image, perhaps as a form of episodic memory (Tulving, 2001), might have been germinal to the creation of *Lavender Mist*.

The Autozoetic Hypothesis .

Autozoesis entails the conscious re-experience of past events in the present. A form of episodic memory might be crucial to the creation of abstract art.

Epistemic Belief and Semantic Categorization

Zachary Estes (estes@uga.edu)

University of Georgia
Department of Psychology
Athens, GA 30602 U.S.A.

Introduction

People tend to believe that membership in an artifact category (e.g., FURNITURE) is a subjectively decided matter of opinion, while membership in a natural category (e.g., FRUIT) is an objectively determined matter of fact (Malt, 1990). I argue that these different beliefs across domains affect categorization in important and predictable ways. If membership in a natural category is an objective, right-or-wrong matter, then categorization should be an absolute, all-or-none decision. But if membership in an artifact category is a subjective matter of opinion, then categorization need not be absolute, but rather may be a matter of degree. Epistemic belief may also affect the confidence with which category membership is judged. If membership in a natural category is objective, then it is possible for the category judgment to be incorrect, and therefore people may sometimes lack confidence in their category judgments. But if membership in an artifact category is subjective, then individuals are entitled their own opinions of the matter. Because opinions are not open to verification or rejection, people may have confidence in their category judgments. Thus, people may be more confident in their judgments of artifacts than of natural kinds.

Experiment 1

In Experiment 1, participants judged the category membership of artifacts and natural kinds, and also rated their confidence in those category judgments. Results indicated that artifact categories were more graded than natural categories. Artifact categories were also judged with more certainty than natural categories. This pattern of results is precisely what one would predict, given the prior evidence that people consider membership in artifact categories to be subjectively decided, while membership in natural categories is believed to be objectively determined. Thus, one may infer that belief affects categorization.

Experiment 2

Experiment 2 attempted to predict an individual's tendency to give graded membership ratings, on the basis of his or her epistemic beliefs. Epistemic beliefs were measured by Schommer's (1998) "certainty of knowledge" questionnaire, which consisted of statements intended to measure one's belief that truth is objective and certain (e.g., "truth is unchanging,"). Participants rated the extent to which they agreed with these statements. They then completed the same categorization task used in Experiment 1. The correlation between "certainty of knowledge" scores and the proportion

of graded responses to artifact categories did not approach significance, $r = -.01$. Critically, however, the correlation between participants' "certainty of knowledge" scores and their proportions of graded membership responses to natural categories was significant, $r = -.37$, $p = .02$. The more a participant believed that knowledge is certain or objective, the less likely she was to provide graded judgments for natural categories. Thus, the belief that knowledge is certain reliably predicted categorization behavior.

Discussion

People's categorization behavior was consistent with their epistemic beliefs (Experiment 1), and moreover, one's epistemic beliefs predicted his own categorization behavior (Experiment 2). Thus, epistemic belief may determine semantic categorization. The claim that lay philosophical beliefs affect categorization is not without precedent. Psychological Essentialism (see e.g., Medin & Atran, 1999) posits that people hold essentialist beliefs, and that these beliefs affect cognition. The present argument is similar. The belief that membership in a natural category is an objectively determined matter of fact leads people to provide absolute judgments of natural kinds, despite the fact that people have relatively low confidence in this objective knowledge. And the belief that membership in an artifact category is a subjectively decided matter of opinion leads people to provide graded judgments of artifacts, and people have high confidence in these subjective opinions. The present experiments, by showing a correlation between epistemic belief and categorization behavior, provide the first direct demonstration of the relation between epistemic belief and semantic categorization.

Acknowledgments

I am especially grateful to Marlene Schommer for the use of her Epistemological Questionnaire. I also thank Elizabeth Barrett, Chris Evans, Roger Gaudreau, and Katie Goodrum for their diligent help with data collection.

Learning from Transformational and Derivational Worked-out Examples

Peter Gerjets (p.gerjets@iwm-kmrc.de) & Katharina Scheiter (k.scheiter@iwm-kmrc.de)

In this research two different solution formats for instructional worked-out examples were compared experimentally with regard to several measures of learning outcomes. A typical example problem from the domain of probability theory used for experimentation is the following:

Problem statement: At the Olympics, 7 sprinters participate in the 100m-sprint. What is the probability of correctly guessing the winner of the gold, silver, and the bronze medal?

The worked-out solution designed for this type of problem according to the *transformational example format* was inspired by a "structure mapping view" of analogical transfer (Gentner, 1983). According to this view, transformations of complex problem representations into another (in terms of structure mapping/ schema induction) are pivotal processes for learning and problem solving. Instructional worked-out examples designed from this perspective may aim at conveying structural problem features necessary to recognize problem categories. Problem categories comprise classes of isomorphic problems that can be transformed into another (using analogy) and that can be represented in a more abstract way (using problem-type schemas). A problem-type schema consists of information about the defining structural features and the appropriate solution procedures for a class of problems. In our experiments the transformational example solutions had the following structure:

Problem features: Selection of 3 sprinters out of seven sprinters; order of selection is important; each sprinter can only be selected *once* (without replacement)

Formula: $A = n! / (n-k)!$

Inserting: $n = 7, k = 3 \Rightarrow A = 7! / (7-3)! = 210$

Result: $1/210 \approx 0.48\%$

Learners are known to have difficulties in acquiring structural problem features and problem categories as well as in adapting solution procedures to novel problems that differ from the problem categories conveyed. Thus, we compared the transformational approach to a different instructional approach that was inspired by AI models of derivational analogy (Carbonell, 1984). The main idea of the derivational approach is to convey knowledge on *how to derive solutions* for problems regardless of their problem category and to abandon the mapping/ categorization of problems as

well as the application of category-specific solution procedures. In our experiments the basic rationale for the *derivational example format* is to decompose a complex event into a sequence of individual events. The overall probability is calculated by multiplying the individual-event probabilities. Contrary to the transformational approach, the solution strategy conveyed in the derivational approach is not seen as a solution schema that is applied to the problem as a whole. Instead it is presented as a sequence of solution steps where each step can be justified (and modified) by concrete features of the problem at hand. Therefore, the derivational example format is characterized by a high modularity. The derivational example format had the following structure:

Rationale: Calculate probability of correctly guessing the winner of each medal; each medal can be taken into account *separately*.

Step 1: 7 possible choices (sprinters), 1 acceptable (winner) $\Rightarrow 1/7$

Step 2: 6 possible choices (winner can't win two medals),
1 acceptable choice $\Rightarrow 1/6$

Additional steps: Analogous procedure

Result: Overall probability: $1/7 * 1/6 * 1/5 = 1/210 \approx .48\%$

In order to compare both example formats two hypertext-based experiments using different dependent measures (e.g., learning time, example processing strategies, problem-solving performance, problem classification, problem comparison) were conducted. The results show a clear superiority of the derivational example format with regard to learning time and problem-solving performance.

The Role of Cognitive Modeling in Enhancing Dynamic Decisions

Cleotilde Gonzalez (coty@cmu.edu)

Social and Decision Sciences Department

Carnegie Mellon University

5000 Forbes Ave. Pittsburgh, PA 15213-3890 USA

Dynamic Decision Making is characterized by multiple and interdependent decisions, autonomous environments, and real-time evaluation and action (Brehmer, 1990). There seems to be increasing agreement on how we make decisions in this type of situations. Decision makers in dynamic environments recognize typical situations and typical responses and use their knowledge to adapt their strategies "on the fly" (Payne, Bettman, and Johnson, 1993; Klein, 1998).

Many cognitive models have been developed in the past decade to investigate different aspects of cognition in these environments: attention and multitasking (Lebiere, Anderson and Bothell, 2001; Altmann and Gray, 2000); judgment and choice in decision making (Gonzalez, Lerch and Lebiere, submitted); and skill acquisition in dynamic situations (Wallach and Lebiere, 2000; Schoppek, Holt, Diez and Boehm-Davis, 2001). These efforts are commendable for focusing on complex, real world tasks. However, the role of cognitive modeling in enhancing decision-making in these situations has been very static and limited.

Traditionally, cognitive models are developed within the context of a task. A synthetic version of the task exists in the form of a computer program, and a cognitive model is developed to interact with such a tool. On the other hand, the synthetic task environment supports the collection of behavioral data and the development of the cognitive model. Theories expand and conclusions are reached about human cognition based on the comparisons between human and model data. I believe that cognitive modeling may and should take a more dynamic role in enhancing decision-making. Creating cognitive models to perceive a situation, combine goals and beliefs, choose a course of action, and react over the environment, is a challenge that we should overcome.

In my current research, I intend to enhance existent cognitive models to take an active, real-time role in decision making and learning. An example of this effort is the cognitive model of instance-based decision-making, developed in the Water purification Plant (WPP) task (Gonzalez, Lerch and Lebiere, submitted). WPP is a resource allocation, scheduling task, isomorph of a real world task in an organization with large-scale logistical operations (the United States Postal Service: USPS) (Lerch, Ballou, and Harter, 1997). WPP is highly dynamic because of exogenous events occurring without the decision maker's control and it is complex because of the number of options

and alternatives to consider at any given time. All these elements interact with the decision maker's actions in a real-time environment, and events occur as the simulation clock is running. Based on an Instance-Based Decision Making framework, I have developed a cognitive model (built on ACT-R) to interact with the WPP task. At present, the model accurately simulates the variability of choice in this dynamic situation and allows strategy adaptation and flexibility. But, the model works off-line, not directly incorporated in monitoring the status of a real decision maker in real-time.

I intend to use this cognitive model to help track and adapt the conditions of WPP in real-time, according to the cognitive necessities of a human decision maker interacting with the task. By tracking each of the actions taken by a human decision maker and monitoring the status of the task environment, the cognitive model would be able to predict the possible contents of working memory and the state of knowledge in the form of instances (See figure). Based on the predicted cognitive status of human decision makers, the cognitive model may give advice to the decision maker in the form of:

1. attracting attention to the parts of the screen that have not been acted on and require awareness according to the environmental status
2. Presenting information in multiple modalities to spread the load to multiple channels
3. Perform urgent actions that the decision maker would not have time or resources to react to

Although simple and limited, I believe that, this effort may demonstrate an active and dynamic role of cognitive modeling in complex situations.

Developing a Framework for Understanding Scientific and Technological Thinking: Notes from a Workshop

Michael E. Gorman (meg3c@virginia.edu)

Division of TCC, SEAS, University of Virginia
Charlottesville, VA 22904-4744 USA

Alexandra Kincannon (kincannon@virginia.edu)

Department of Psychology, University of Virginia
P.O. Box 400400, Charlottesville, VA 22904-4400 USA

On March 24, 2001, Alexandra Kincannon, Ryan Tweney and Michael Gorman convened a workshop on cognitive studies of science and technology at the University of Virginia (Gorman, Kincannon, & Mehalik, 2001). We assembled a multi-disciplinary group of practitioners to discuss the latest research and methodologies, identify the stumbling blocks to advancement in this area, and think about directions for the future. The workshop was dedicated to Herb Simon, who was slated to participate.

Two questions became central themes. First, how can we combine in vitro experiments with in vivo case studies of actual practice? Results obtained in the laboratory may have low ecological validity. Fine-grained case studies are often domain-specific and hard to generalize.

Second, how can we deal with academics' attachments to their own hypotheses and methods? Researchers tend to overgeneralize hypotheses developed under specific in vitro or in vivo conditions.

One way of avoiding this kind of overgeneralization is to combine in vitro and in vivo methods. With help from workshop participant David Klahr and others, we developed a preliminary framework based on the idea of searches in multiple problem spaces, and identified which had been investigated in vitro and which in vivo. For example, hypothesis and experiment spaces have been investigated both in vitro and in vivo, but function and design spaces have only been studied in vivo. This approach helps identify areas for future research.

The workshop illustrated that frameworks can be shared and that in vitro and in vivo studies have to complement one another. Theories need to deal rigorously with the distributed character of scientific and technological problem solving. We hope this workshop will suggest directions for future applications as well as research.

See <http://repo-nt.tcc.virginia.edu/cogwksshop/index.html> for more information about the workshop and the participants.

Automated Detection of Strategies in Free Text Responses

Anthony Harrison (anh23@pitt.edu)

Lelyn Saner (les53@pitt.edu)

Christian D. Schunn (schunn@pitt.edu)

Learning Research and Development Center, University of Pittsburgh
3939 O'Hara St., Pittsburgh, PA 15260 USA

When solving problems, people often use a wide array of different strategies. Effective teaching often requires isolating what strategies students are using (or not using) in order to more effectively structure the instructional intervention. Nowhere is this truer than in the realm of intelligent adaptive tutors. The classification of strategy use in complex domains presents an interesting challenge to intelligent tutors. This is made even greater if the strategies are to be extracted from free text responses given by the students.

To this end, we have been using Latent Semantic Analysis (LSA) as an automatic strategy classification tool. LSA is a computational tool that extracts the co-occurrence of words in a corpus. Through high-dimensional matrix decomposition, LSA is able to produce a "semantic-space" allowing all experienced words, phrases, and sentences to be represented as vectors within that space. The more similar the vectors are to each other, the more similar their meanings. As LSA has matured, some have suggested that it may be a psychologically plausible theory of semantic learning. We remain noncommittal in this regard, choosing instead to rely upon LSA in its original capacity as a fast and efficient text-processing tool.

Strategy Classification

Our current endeavor is to use LSA to intelligently classify strategy use in day-to-day military operations. The hope is that by accurately classifying young officers' strategy uses, we can develop tutoring systems to broaden their range of strategies as well as train them to more appropriately apply the strategies.

The strategy classification system relies upon a series of key steps. First the LSA semantic space was generated based on a set of military handbooks, training documents, and pedagogical examples. Free text responses to military scenarios were collected from officers in training as well as experienced military officers. These were then human coded into different strategy categories. The responses were then fed into LSA to generate their vector representations in the semantic space. These two sources yielded two databases of semantically coded (vectors in semantic space) strategies. The novice database (officers in training) is used as a descriptive reference, while the expert database (experienced officers) provides the normative references. The final steps are to take the free text responses of other

novices to the same vignettes, transform them into vectors in semantic space, and then each of these vectors is compared against those in the databases. Since they are vectors, the cosine between the two serves as a simple similarity score. As similarity increases, the cosine value will approach one. This process yields a ranking of similarities to the descriptive database, where the classified strategy is merely the most similar. Additionally, since we have a sample of strategy exemplars, we can also look at the distribution of similarity scores across strategies. This yields a simple measure of *confidence*: the greater the number of high similarity matches within a given strategy gets, the more confident we can be that it is representative of that strategy.

At this early stage in the development of the system, we were pleased to see that LSA was classifying strategies about as well as our human coders, with almost equivalent inter-rater reliabilities. This is a significant accomplishment given how limited our semantic space is currently (only 100,000+ words, in comparison to the millions of most other LSA corpora), and the limited scale of our descriptive database (10 strategies, approx. 16 exemplars each).

Future Directions

Aside from increasing the scale of both the semantic space and the reference databases, we hope to begin working on the tutoring system proper. This will mean developing a training system that adapts to the strategy use of the individual to provide sufficient scaffolding to enable them to explore alternative strategies, as well as to learn how to appropriately apply them. Then, as the student progresses through the tutor, the normative database (provided by experienced military officers) will come into greater play.

ACT-R/S: A Computational and Neurologically Inspired Model of Spatial Reasoning

Anthony M. Harrison (anh23@pitt.edu)

Christian D. Schunn (schunn@pitt.edu)

Department of Psychology, University of Pittsburgh
3939 O'Hara St, Pittsburgh, PA 15260 USA

The field of cognitive modeling has seen a recent push in two major areas: embodied cognition, and neurological realism. No longer is it sufficient to show that a model of cognition can produce a specific behavior without actually interacting with its environment in some way, be it a real environment or simulated. Nor can psychologists ignore the fact that for every system, representation, rule, and computation proposed there must be some underlying neurological reality behind it. With both these constraints in mind, we set out to develop an extension to ACT-R (Anderson & Lebiere, 1998) allowing it to enter into a three-dimensional world in a neurologically plausible manner.

ACT-R/S (spatial) relies specifically upon three processing modules, only two of which are new to the architecture. Each of these modules has been shown to be both behaviorally and neurologically separate. The representations and computations of each of the systems are similarly distinct.

Three Visiospatial Systems

Visual System The primary function of a visual system is to identify a set of visual features as an object. The visual system needs to be able to take fine-grained detail and through special processing, recognize an object. A feature of this system is that it is able to perform its task based off of basic two-dimensional retinotopic information. An object's depth or spatial extent is not typically necessary for its accurate identification. This functionality is currently available in Mike Byrne's ACT-R/PM (perceptual & motor extension).

Neurologically, the visual system is seated in the primary visual areas as well as the ventral visual processing stream which limits processing to fine detail, color perception, local form perception, visual scanning and visual feature analysis (see Previc, 1997 for review).

Manipulative System When it comes to grasping and manipulating objects, we need to be able to represent them in a manner that will enable us to effectively prepare the motor system for the task ahead. The manipulative system is concerned entirely with a metric, geon-based (Biederman, 1987), three-dimensional representation of objects. These representations are then typically fed to the motor system permitting the development of complex motor programs. The manipulative system can represent almost any three-dimensional object, but its primary purpose is to support actual manual manipulation.

The manipulative system relies upon the dorso-lateral visual stream as well as the parietal cortex. The involvement of the parietal cortex is not surprising given that these tasks often involve actual manipulation. However, when subjects are asked to imagine object rotations, the parietal cortex is still often activated (see Previc, 1997 for review).

Configural System The configural system is concerned with representing objects in space to facilitate navigation. It represents the world around us as spatial blobs that need to be navigated around, above, or below. Its representations are nowhere near as precise as those found in the manipulative system. It encodes the locations of objects in terms of egocentric vectors that are continuously updated through path-integration. The utilization of multiple landmarks allows the system to uniquely position itself in space and return to locations at later points in time.

The discovery of "place-cells" in the rat hippocampus has been viewed as the definitive location of cognitive-maps in the brain (O'Keefe & Nadel, 1978). Recent research has shown that the parahippocampal regions are more important in primate navigation but they still represent some form of a map of the environment. Our own meta-analysis brings the "egocentric" assumption of "place-cells" into question, hence our usage of egocentric vectors in the configural representations.

Summary

With the proposal of two additional processing systems that specialize specifically in three-dimensional processing, it is hoped that we will be able to expand the range of phenomenon that computational cognitive models can represent. We present this not only for the ACT-R architecture, but also so that other architectures might get a foothold in three-dimensional embodiment.

Belief Revision and Reasoning

Uri Hasson (uhasson@princeton.edu)
Psychology Department, Princeton University
Princeton, NJ 08544 USA

Philip N. Johnson-Laird (phil@princeton.edu)
Psychology Department, Princeton University
Princeton, NJ 08544 USA

Which beliefs do you abandon when you discover that their consequences conflict with the facts? Suppose, for example, you have the following beliefs:

Belief 1: If the drink is cold, then it is caffeinated.

Belief 2: The drink is cold.

You make an inference of the form known as *modus ponens* (MP): The drink is caffeinated. But then you discover:

Fact: The drink is not caffeinated.

You are likely to reject any belief that is dubious or from a dubious source. Perhaps you will be more likely to reject a simple categorical assertion, such as belief 2, than a generalization, such as belief 1 (Revlis, 1974). Conversely, you will be more likely to retain believable generalizations (Dieussaert et al., 2000, Politzer & Carles, 2001). But, if your beliefs are equally plausible, then a pertinent factor is whether there is an apparent conflict between the facts and your beliefs. According to the theory of mental models, such conflicts can occur (Giroto et al., 2000). The model theory postulates that belief 1 calls for two mental models:

Cold Caffeinated

The first model represents the possibility in which the antecedent is true; the second model has no explicit content but represents the possibilities in which the antecedent is false. The model of the fact:

Not caffeinated

conflicts with the explicit model above, and so you should reject the conditional. In fact, the conflict is apparent, not real.

Consider a contrasting case in which you believe:

Belief 1: If the drink is cold, then it is caffeinated.

Belief 2: The drink is not caffeinated.

You can make an inference of the form known as *modus tollens* (MT), but its conclusion is contradicted by the fact:

Fact: The drink is cold.

The fact matches the explicit model of the conditional, but is not represented in the model of the categorical premise (belief 2). Hence, the theory predicts that you will be more likely to reject the categorical premise.

We carried out experiments to test these predictions. Participants were presented with scenarios such as the one above, and were asked to decide which of the beliefs they found more credible. Half of the scenarios were in the form of conflicts with MP inferences, and half of them were in the form of conflicts with MT inferences. In addition, the consequent of the conditional statement was either

affirmative or negative. And in half the scenarios, the conditional statement was the first belief in the set, and in the other half it was the second belief.

The participants were more likely to reject the conditionals in the MP scenarios (60% rejected) than in the MT scenarios (47% rejected; see also Dieussaert et al., 2000; Elio & Pelletier, 1997), but the difference was reduced when the conditionals had negative consequents. There was also a bias to believe whichever statement was presented first: for MP scenarios, the conditional was more believable when it came first in the set, but less believable when it came second. But, for MT scenarios, the effect of order was diminished.

When individuals notice the MP inconsistency, then they can readily reject the conditional, especially when it is the most recent statement in the set. MT inferences are harder, but individuals can also notice the inconsistency by, in effect, converting the scenarios into MP inconsistencies. They use the fact and the conditional to draw a conclusion, and then they notice that the conclusion conflicts with the categorical belief. And so they reject this belief.

We conclude that belief revision depends on how individuals represent their beliefs, and on how they reason about them. They may reject a belief because it merely appears to be inconsistent with the facts.

Recency Effects (REs) have been well established in both memory and probability learning paradigms. However, these effects have received relatively little attention, and virtually no empirical investigation, in research on multiple-cue category learning.

Some category learning models do make specific a priori predictions regarding REs. In particular, simple, static REs arise naturally in models incorporating the δ -rule, an error-driven learning mechanism (Gluck & Bower, 1988; Kruschke, 1992). Specifically, the δ -rule implies that responses are based on a weighted average of past cases, with recent cases receiving more weight. Weights drop at an exponential rate with temporal distance. Exemplar models make no a priori predictions regarding RE, but can mimic δ -rule predictions by explicitly incorporating exponential trace decay (Nosofsky, Kruschke, & McKinley, 1992). Both of these approaches predict RE to be unresponsive to characteristics of the task environment.

The present research contrasts this assumption with the alternative possibility that people explicitly test hypotheses concerning the predictive validity of recent outcomes. The latter idea implies that the magnitude of recency effects will adapt to the level of autocorrelation in the category sequence.

Method

Participants ($n=100$) engaged in a simulated medical diagnosis task in which they assigned each of a series of 150 hypothetical patients to one of two fictitious diseases based on the presence or absence of 3 symptoms, with outcome feedback given after each trial.

The experiment consisted of three conditions based on the manner of autocorrelation present in the sequence of disease outcomes. In the *positive* condition, each patient's disease matched that of the previous patient with 70% probability; in the *negative* condition that probability was 30%. Trials in the *control* condition were independently sampled (i.e., a 50% transition probability). For each subject, the diseases were first randomly generated according to the condition, and then the symptoms were randomly generated with probabilities dependent on disease outcomes.

Results

A logistic regression model was fitted to the data from each subject to determine the degree of influence of both present and past information on that subject's responses. The predictors in this model were the three symptoms, the

disease of the previous patient (Disease_{n-1}), the similarity of the previous patient's symptom profile with that of the present patient (C_{n-1}^n , given as the number of matching minus the number of mismatching symptom dimensions), and the interaction $\text{Disease}_{n-1} \times C_{n-1}^n$.

The regression coefficient for Disease_{n-1} was significantly higher for subjects in the Positive condition as compared to Control, indicating a heightened recency effect (Fig. 1). The reverse effect was not found for the Negative condition, despite its logical symmetry with the Positive condition.

In addition, the coefficient for $\text{Disease}_{n-1} \times C_{n-1}^n$ was significantly positive in all 3 conditions, showing that cue commonality moderates RE.

Figure 1: Subjects' use of past information, by condition

Discussion

Reliance on recent outcomes increased dramatically when those outcomes were positively related to the current case. No corresponding effect was found for negatively related recent outcomes. In fact, no overall RE was found in the negative and control conditions. These effects are not anticipated by the standard proposal that impact of outcomes simply decays exponentially with time. People appear to assess the predictive validity of recent events, but are nevertheless biased towards expecting a positive relationship.

The Roles of Context and Working Memory in Probability Matching

Alexandra P. Kincannon (kincannon@virginia.edu)

Department of Psychology, University of Virginia
P.O. Box 400400, Charlottesville, VA 22904-4400 USA

Introduction

Probability matching, where a participant's choice frequency matches the probability of an alternative, is the modal response strategy in many probabilistic choice tasks. According to traditional norms, the probability matching strategy results in a sub-optimal payoff, compared to the utility maximizing strategy of always choosing the most probable alternative. Some researchers, however, have argued that probability matching is evolutionarily adaptive in certain environments (e.g., Gigerenzer, 1996) and recent evidence suggests that use of the matching strategy is sensitive to different kinds of feedback and incentives (Gallistel, 1990; Wolford, Newman, Cutler, & Miller, 2001).

Others have applied a dual-systems approach to explain the strategies that participants use in probabilistic choice and other tasks (Stanovich & West, 2000), finding that those who use a utility maximizing strategy have higher cognitive ability on average than those who use a probability matching strategy. This evidence supports the theory that the two strategies are products of two different reasoning processes; one that is rule-based and analytic and one that is based on evolutionarily derived heuristics.

The present experiment explores the roles of working memory and task context in probability matching. These factors are proposed to differentiate between the two reasoning processes. Analytic processing requires working memory resources; thus taxing these resources with a secondary task should reduce the use of the maximizing strategy in the probabilistic choice task. Heuristic processing requires a meaningful, socially relevant context; thus an enriched context should increase the use of the matching strategy in this task.

Method

A 2x2 between-participants design was used with two levels for each of the independent variables. Participants were assigned at random either to do the probabilistic choice task by itself or in parallel with a random number generation task (single vs. dual task condition). Half the participants saw a contextually sparse version of the choice task in which there were two blank squares on a computer screen and they had to guess which square would not change color. The other half saw a contextually enriched version in which there were two parking lots and they had to guess which lot would not be ticketed. Participants received feedback after each trial. The experiment was programmed to make the target event occur 75% of the time at the location on the left side of the screen.

Results and Discussion

The 150 trials were divided into five blocks of 30 and a difference from matching score was calculated for each block by subtracting the number of times the left side was chosen from the number of times the target event occurred on the left. There was a significant main effect for both the task condition and the context condition (see Figure 1.). In the first block, participants in all conditions chose either side with equal frequency. In the last block, participants in the single task/rich context condition were more likely to use a maximizing strategy, whereas participants in the other conditions were more likely to use a matching strategy.

These findings suggest that analytic processing resources are needed to use the maximizing strategy, as was predicted. Surprisingly, the enriched context facilitated a maximizing, rather than a matching strategy.

Figure 1: Single task condition and rich task context facilitate a utility maximizing strategy. Filled shapes = Sparse context, open shapes = Rich context; circles = Dual task, triangles = Single task.

The Structure of Linguistic Spatial Representation

A test for psychometric structure using Japanese spatial terms

Takatsugu KOJIMA (kojima@cpsy.mbox.media.kyoto-u.ac.jp)

Takashi KUSUMI (n50609@sakura.kudpc.kyoto-u.ac.jp)

Faculty of Education, Kyoto University
Sakyo-ku, Kyoto 606-8501 Japan

Introduction

Although it is not clear whether our system of spatial representation as a whole (integrated spatial representation) is structured initially by perception or by language, it is certain that forms of spatial representation generally are ultimately based largely on perception, especially on vision, and on language. Furthermore, when we encode or categorize forms of spatial representation, we do so following systematic rules that are founded on the structures of spatial representation formed by vision, language and so on.

The question remains, then, whether these spatial structures resemble each other? If so, are they grouped in any way? In addition, do they connect with each other, and, if they do, what is the nature of the relation between the specific spatial representational structures formed by vision and by language? According to Hayward and Tarr (1995), the spatial structure encoded by language (e.g., above, below) seems to be based on, and to correspond to, the spatial representational structure based on perception. Crawford, Regier and Huttenlocher (2000), however, have insisted that these structures do not correspond.

Both Hayward and Tarr (1995) and Crawford et al (2000) examined this issue from the viewpoint of categorical prototype and boundary. In linguistic spatial categorization, prototypes and boundaries are dependent on what spatial terms are used. Therefore, their method is not appropriate for comparing spatial structures.

In this study, instead of prototypes and boundaries, we examined fit patterns for four Japanese spatial terms (*ue*, *shita*, *hidari*, *migi*) using Thurstone's law of comparative judgment (case V). From this fit distribution and the prototypical spatial structure of visual representation (Huttenlocher, Hedges, and Duncan, 1991), we investigated whether the spatial structure of perceptual representation corresponds to that of linguistic representation.

Method

Ten Japanese graduate and undergraduate students participated. Stimuli were generated by an IBM/PC compatible computer and presented on a CRT at a viewing distance of approximately 115cm. For each trial, an instruction word would first appear in the center of the screen for 1000ms. Then, a black square ($11^\circ \times 11^\circ$ side) was centered as a reference object, and two black dots ($0.12^\circ \times 0.12^\circ$ diameter) were randomly presented as target objects, occupying 21 fixed locations that were based on a former experiment (Kojima & Kusumi, 2002). Four Chinese characters (), each of which expresses spatial

locations (e.g., "*ue*") in Japanese is nearly equal to "above" in English, and, in the same way, "*shita*" to "below", "*hidari*" to "left" and "*migi*" to right) were used as the instruction words in a square ($11^\circ \times 11^\circ$ side). The participants were required to compare the locations of the two dots in relation to the reference object, and to choose the dot that best suited the location expressed by the prior instruction word.

Results and Discussion

The paired comparison data were processed and scaled by Thurstone's law of comparative judgment (case V). The fit patterns of the four Japanese spatial terms are shown in Fig1, based on scaled value. Here, the width and depth are equivalent to the horizontal and vertical frame lines on the CRT. The height expresses the scaled value (from -3.00 to 3.00). This fit pattern differs from that of the prototypical structure; It shows a less simple gradient pattern.

From this pattern and former studies' result (Huttenlocher et al, 1991), we supported the suggestion of Crawford et.al (2000). That is, we also found that the structure of visual spatial representation does not correspond to the structure of linguistic spatial representation.

Figure 1: The fit pattern of four Japanese spatial terms

The Effect of Attentional Distraction in the Tempo-Naming Task

Laura Leach (lleach@gmu.edu) and Christopher Kello (ckello@gmu.edu)

Department of Psychology, George Mason University
4400 University Drive, Fairfax, VA 22030 USA

Errors in word naming can reveal dysfunctions in the component processes of word reading. An abundance of regularization errors (e.g., naming PINT to rhyme with MINT) suggests an over-emphasis on sub-lexical spelling-sound correspondences relative to lexical knowledge. An abundance of lexicalization errors (e.g., naming WIFE as WHITE) suggests a malfunction in the influence of lexical knowledge. An abundance of positional errors (e.g., naming BROAD as BOARD) suggests a malfunction in the positioning of letters and/or sounds.

Kello and Plaut (2000) introduced the tempo-naming task as a method for inducing naming errors under extreme pressure for speeded responding. The results of three experiments showed that lexicalization errors predominated compared with regularization errors. They interpreted this pattern as indicating that pressure for speed caused an increase in the emphasis on lexical knowledge in the process of converting print to sound. Emphasis on lexical knowledge can also be found under manipulations of strategic control (Herdman, 1992), and in the reading errors that define phonological dyslexia (Coltheart, 1996).

In the current study, we examined the effect of distraction of visual attention on performance in the tempo-naming task. Attentional distraction was hypothesized to interfere with the process of identifying and positioning the letters of a word stimulus. Errors were used as window into the effect of attentional distraction on processes of word reading.

Method

Participants

Twenty undergraduates participated in the experiment for course credit. All participants reported English as their native language, and all had normal or corrected vision.

Stimuli

The experiment consisted of 600 monosyllabic words, sampled from a full corpus of English words to preserve the distributional characteristics of the full corpus. Words varied in frequency and regularity. For each participant, each word was randomly assigned to one of six blocks such that there were 100 words per block.

Procedure

On each trial, five beats of a simple audiovisual tempo were presented, and a printed word was displayed on the fifth beat. The tempo was varied between 200 ms and 650 ms (in steps of 50 ms), and each word was assigned to each tempo

twice across participants. Participants were instructed to name the word in time with the sixth beat, and feedback on timing was given on every trial. Visual distraction was created by flashing white disks of varying size in random positions on the screen during stimulus presentation.

Results and Discussion

As tempo decreased (i.e., more pressure for speed), naming latencies and durations decreased, and overall error rates increased. These results replicated Kello and Plaut (2000).

The percentage of different types of errors is graphed as a function of tempo in the figure below. Lexicalizations were much more frequent compared with regularizations, and lexicalizations increased with faster tempos, but regularizations did not. The rate of lexicalizations was greater than that found in a comparable experiment (not reported here) in which there was no attentional distraction. Other error types included nonwords, stutters, and garbled pronunciations.

Results indicated that attentional distraction caused an increase in the emphasis on lexical knowledge. Future analyses are planned to examine the effect of attentional distraction on the rate of positional errors.

Why Animated but not Static? The Spatial-Temporal

Terence C. P. Lee (faypul@graduate.hku.hk)

Albert W. L. Chau (awlichau@hku.hk)

Background

Past research has shown that pictures in general enhance learning with text. Glenberg & Langston (1992) found that pictures compatible with text facilitate the learning of a procedural concept with concurrent steps. Glenberg & Kruley (1992) evinced that pictures assist anaphor resolution, thereby improving comprehension.

One of the major theoretical constructs adopted to account for such facilitatory effect is the dual-code theory by Paivio (1971), which suggests that information could be stored either verbally or visually, and that these codes together lead to better retention than either one alone.

Owing to the advancement in information technology, multimedia instructional materials, such as computer-generated animation, have become popular. Compared with static pictures, animation facilitates learning only under more specific conditions. Rieber (1991) showed that students with animated presentation outperformed those with static presentation, but only when frames were presented in chunks. Schnotz, *et al.* (1999) showed that animation better assists learning than static pictures for individual learning, but not cooperative one, which leads to cognitive overload. Mayer and Sims (1994) demonstrated that high-spatial ability students benefit more from contiguous animation than their counterparts. Large, *et al.* (1996) found that animation improves the comprehension of a procedural text more than a descriptive one.

Hypotheses

The aforementioned findings converge to suggest that animation learning demands additional cognitive processing that consumes extra cognitive resources, compared with static-picture learning. In the light of 1) the advantageous position of high-spatial ability students, 2) the facilitatory effect upon learning sequential concepts, and 3) the essential disparity between animated and static pictures, it is postulated that the animation-over-static-picture advantage, when it occurs, is attributable to better spatial-temporal coding in the former condition.

Methodology and Findings

The design was a modified version from the study by Moreno and Mayer (1999). The participants were forty-four undergraduates enrolling in Introduction to Psychology at the University of Hong Kong. Participants in the animation-narration condition viewed an animation of 190 seconds on lightning formation, while participants in the static-picture-narration condition viewed 11 static pictures that were snapshots representing critical steps of lightning formation extracted from the animation. After the learning section, participants were tested with three tasks: 1) matching verbal

labels with to-be-circled objects, 2) verbal recall of narration and 3) sorting the sequence of 11 pictures, which were the pictures shown in the static condition. The last measure, which had not been adopted in previous studies, was developed to assess spatial-temporal coding.

One-tailed independent-samples *t* tests showed that the animation-narration group outperformed static-picture-narration group, on the matching task ($t(42) = 2.630, p = 0.006$), the verbal-retention task ($t(42) = 3.077, p = 0.02$) and the visual-spatial-retention task ($t(42) = 1.895, p = 0.0325$).

Discussion

Results showed that animation plus narration is a better combination than static pictures plus narration in facilitating learning. The former led to stronger verbal and visual representational connections, and closer referential connections between the two modules, all of which are beneficial to the learning of a sequential concept. In addition, animation was found to be superior to static graphics in assisting spatial-temporal coding. These findings are consistent with a modified version of Paivio's dual-code theory.

Domain Knowledge and False Memory

Yuh-shiow Lee (psyysl@ccu.edu.tw)

Han-yu Lin (hanyu@nsl.mit.edu.tw)

Department of Psychology, National Chung-Cheng University
Chiayi, 621, Taiwan, ROC

Introduction

Many studies have demonstrated the power of schema or knowledge structure in organizing incoming information, which led to various kinds of memory errors. What a person already knew determined whether and how information would be remembered. Thus, it is clear that there is a close link between cognitive processes and structures and the types of memory errors committed. Based on this logic, the present study examined how participants' prior knowledge affects memory errors. This study used the DRM paradigm to examine false memory produced by a group of industrial design experts as compared to the control group.

In the DRM paradigm, participants study list of semantic related words (bed, awake, rest...) that are all related to a critical word that is not presented (sleep). High levels of false memory for lures (e.g. sleep) have been demonstrated in tests such as free recall and recognition (e.g., Roediger & McDermott, 1995). Studying expert behaviors offers a unique window into human cognition. While experts' behaviors on chess were the most researched area, a wide range of domains has been examined and various methods have been used in this area. The clearest finding from these studies was that memory performance on meaningful stimuli has found to be correlated with domain expertise. However, very few studies in this area have focused on the pattern of errors as affected by domain expertise.

McEvoy, Nelson, and Komatsu (1999) looked at the influence of preexisting knowledge on the production of false memory. They found that the probability of producing false memories in free recall varied with the strength of connections from the list words to the critical word and the density of the interconnections among the list words. In addition, false recognition was more likely when the list words were more densely interconnected. McEvoy et al. (1999) determined the association strength based on the word association norm and examined how the strength relates to false memory. Since the association strength between words develops through experiences, it is reasonable to assume that for the words that come from specific domain knowledge, experts of that domain and novices would have different types and strength of association. This would lead to different types and amount of false memory. This study investigated whether domain specific knowledge would induce or reduce false memories. A group of experts and novices were tested on words either related or unrelated to their knowledge of expertise.

Results and Discussion

Two types of semantically related list items were used in this study. One type of items were words selected from technical terms used in the domain of industrial design whereas the other type were common words. Four groups of participants were recruited: senior and junior non-industrial design students and industrial design students. Results showed that for the design-related lists, senior industrial design students not only performed better on both recall and recognition, but also had a higher rate of false recognition. In addition, age had an effect on the false recognition of common words, while the rate of false recognition of design-related terms was mainly determined by participants' domain knowledge. These results support the view that domain knowledge plays an important role in creating false memory.

Table. Mean Percentages of Correct Recall, Recognition and False Recognition as a Function of Age and Domain Knowledge

	correct recall		correct recognition		false recognition	
	common words	design-related words	common words	design-related words	common words	design-related words
Senior						
non-experts	.71	.49	.95	.86	.50	.29
experts	.73	.69	.94	.92	.57	.44
Junior						
non-experts	.72	.52	.94	.86	.35	.28
experts	.72	.52	.93	.89	.38	.28

Acquisition of Landmark Knowledge from Static and Dynamic Presentation of Route Maps

Paul U. Lee (pauly@psych.stanford.edu)
Department of Psychology, Bldg. 420
Stanford, CA 94305 USA

Heike Tappe & Alexander Klippel ([tappe, klippel]@informatik.uni-hamburg.de)
Department for Informatics, University of Hamburg
Vogt-Kölln-Str. 30, 22527 Hamburg, Germany

Introduction

Route maps have recently gained much attention as effective tools to convey route information. Benefits of maps are attributed to their ubiquitous existence in culture and their analogous properties representing spatial knowledge. Route maps have become widely available through the internet and within on-board navigation systems. Despite their prevalence, optimal design criteria are still missing.

For example, route maps integrated in on-board navigation systems present routes dynamically with a moving dot that traverses a map. In contrast, internet maps present information statically with lines representing the route. At first glance, dynamic, animated presentation seems to be more effective than static one. (e.g. Nathan, Kintsch, & Young, 1992). However, advantages of animation may be due to other factors, such as interactivity or inclusion of information not present in static conditions. Furthermore, other studies fail to demonstrate superiority of animations at all (e.g. Morrison, 2000).

Extending research on effects of static vs. dynamic route presentation on conceptualization and memory (Klippel, Tappe, Habel, submitted), we examined the influence of presentation mode on memory for landmarks.

Dynamic vs. Static Presentation of Maps

Material and Procedure

Participants learned a route from a map of a fictitious town. The route was presented to them either as a solid line (i.e. static), a moving dot (dynamic), or a dot superimposed on a line (mixed).

The participants viewed the map three times, each for 1.5 minutes. Afterwards, they were given a blank map with only the streets and were asked to recall the landmarks.

Recall Memory of Landmarks

In the dynamic condition, landmarks at turning and non-turning intersections were recalled equally well (49.4% vs. 48.8%), but in the static condition landmarks at turning intersections were remembered more often (52.9%) than at

non-turning intersections (43.8%) (see Table 1). Since landmarks at turns are more critical to route directions, we conclude that static displays of route information is preferable over dynamic displays.

	Turns	Non-turns	Total
Dynamic	49.4	48.8	49.1
Static	52.9	43.8	48.4
Mixed	57.7	41.5	49.6

Table 1: Proportion of recalled landmarks (in %)

Surprisingly, in the mixed condition participants recalled even more landmarks at turns (57.7%) than at non-turns (41.5%). The combination of different presentation modes and the resulting memory improvement for vital route information support findings on the benefits of redundant information displays (Hirtle, 1999).

Bongard problems and symbolic approaches: a skeptical look.

Alexandre Linhares (linhares@fgv.br)
EBAPE/FGV, Praia de Botafogo 190
Rio de Janeiro 22257-970, Brazil

Introduction to Bongard Problems

Three decades ago the intelligence theorist Mikhail Bongard (1970) posed an outstanding challenge to artificial intelligence, bringing a remarkable set of 100 visual pattern understanding problems where two classes of figures are presented and the pattern recognizer (either a human or a machine) is asked to identify the conceptual distinction between them. Sometimes the classes are opposite in terms of this conceptual distinction, such as large figures versus small figures, and other times there may be properties or relations holding between boxes in one class, but not in the other, such that there is always some aspect to distinguish the classes.

Figure 1 displays two very simple Bongard problems. One of the most important characteristics of such problems is that, although humans can generally solve them intuitively, their automation is simply daunting: there is always much relevant information to be perceived and much irrelevant information to be discarded.

Figure 1: Bongard problems BP#91 and BP#38. What abstract aspect distinguishes the boxes on the right (class 1) from the boxes on the left (class 2)? [From M.M. Bongard (1970) *Pattern Recognition*, Spartan books]

A philosophical problem

Let us focus on the following issue: suppose that a specific Bongard problem includes the following box shown in figure 2. Would it be appropriate (as done in Saito and Nakano 1994; Saito and Nakano 1995) to

discard the raw geometrical information in favor of a simple symbolic description, such as that presented?

TRIANGLE (coordinates, line_width, ... remaining properties)
LINE_SEGMENT (coordinates, ... remaining properties)

Figure 2: Raw geometrical information versus symbolic descriptions.

This is the core question of our investigation. We argue that such approach is unattainable, as it leads to the inadequate philosophical grounds of *metaphysical realism*. Purely symbolic representations are not capable of containing all forms of concepts and categories expressed (and expressible) in Bongard problems. Furthermore, they lead to inadequate architectural models, which can easily be seen to falter (Linhares, 2000; see also Hofstadter 1979, Hofstadter 1995a, Hofstadter 1995b). Finally, we propose that the philosophical grounds sketched in Smith (1984) are sound alternatives to current theory.

Language-Like Representation in Embodied and Situated Cognition: A Case Study of a Situated Robot's Planning

Hsi-wen Liu (hwliu@pu.edu.tw)

Division of Humanities, Providence University
200 Chung-Chi Rd, Shalu, Taichung County 433, Taiwan

Interests in embodiedness and situatedness have increased in all disciplines of cognitive science (Clark, 1999). Such interests generally concern the complex interplay between robotic (or neural) systems and their local environments. A number of theorists and philosophers with such interests cast strong doubt on the need of a rule-based search and even the need of overall *internal* representations (Brooks, 1991; Beer, 1995; Keijzer, 1998).

Also with those interests, Andy Clark and some co-authors raise significant reasons for reconsideration regarding the above doubt (Clark, 1997ab, 1999; Clark and Grush, 1999; and others). The gist in general is that in the above systems internal representations can exist, by playing a two-fold role. On the one hand, the internal representations in the systems constitute descriptions of the world, and on the other, these representations serve as *internal* representations/codes to *control* those systems' tight coupling agent-environment interactions. With such a two-fold role, those internal representations are named *action-oriented representations* (Clark, 1997ab, 1999). This two-fold role has been exemplified by a number of robotic architectures with on-line control of situated activities (e.g., see Mataric's TOTO discussed in Clark (1997ab, 1999)). A question with the above theory of action-oriented representations is whether some of those representations can be characterised in language-like codes. If the answer is yes, it would constitute a link between the situated-and-embodied approach and traditional cognitive science.

Conforming to the above theory of action-oriented representations, this work contends that the answer is indeed yes. That is, language-like codes can play the above two-fold role in the control of tight coupling agent-environment interactions. This claim is exemplified by the robot arm designed by Maes (1990).

The robot activities, as Maes (1990) sees, lead (though not in terms of abstract thoughts) to the *planning* of various actions in support of a goal—catching an appropriate tool to paste sand on a board. The architecture of that robot arm is hybrid. It consists of several *action modules*, which perform certain motor actions. The architecture of each action module includes *both* symbolic codes (i.e. language-like codes) which describe environmental conditions (or arm states) *and* the control over the (numerical) energy flowing across those action modules. When the robot system observes, or initiates an action, those modules change their inherent energy and their condition lists of the environment (or the arm states). An action module initiates its action, when the energy flowing in the module goes beyond a certain threshold. Yet, the energy flowing in a

certain module may go below its threshold and hence need a fine-tuning of the energy flowing among certain relevant modules, and even a fine-tuning of the threshold itself.

The present work argues that the language-like codes in the architecture of Maes' (1990) robot arm play the aforementioned two-fold role of action-oriented representations. The steps of argument are as follows.

1. The architecture of the robot arm clearly adopts certain language-like codes, which describe certain conditions.
2. There is a limited degree of searching among those language-like codes, which serve as initiating conditions of the action to be carried out by an action module.
3. The activities of the robot arm are situated, because of the tight coupling agent (arm)-environment interactions.
4. The computation for the control of the above interactions is embodied, because the energy spreading among the relevant action modules (and even a threshold itself) is sensitively fine-tuned in response to the recurrent re-try of initiating a single module's action.

As the above argument shows, the language-like codes in the architecture of Maes' (1990) robot arm play the two-fold role of action-oriented representations, in support of the robot's situated and embodied activities. This constitutes a link between situated-and-embodied approach and traditional cognitive science.

The Comprehension of Novel Noun-Noun Compounds: The Influence of Out-of-Context Interpretations on In-Context Understanding

Dermot Lynott (dermot.lynott@ucd.ie) and Mark T. Keane (mark.keane@ucd.ie)

Department of Computer Science, University College Dublin, Belfield, Dublin 4, Ireland.

Introduction

A key question for language research, and in particular conceptual combination, is the dependence of in-context understanding on out-of-context meanings. Gerrig & Bortfeld (1999) contrast two views of conceptual combination comprehension in context, the interdependence and independence views. The *interdependence view* states that out-of-context meanings influence the in-context comprehension of novel combinations while the *independence view* (adopted by Gerrig and Bortfeld) maintains that context is the prevailing factor and prevents the activation of interpretations that might normally be available out of context. We test this hypothesis by generating a set of compounds whose interpretations differ in their frequency of production out of context and then varying the contexts in which the high-frequency or low-frequency interpretations are embedded. We can then establish whether these out-of-context interpretations have a bearing on in-context processing.

Experiment 1

We collected participants' out-of-context interpretations for novel noun-noun compounds and categorised them by their frequency of production. High-frequency (HF) and low frequency (LF) interpretations for each compound were selected from these frequency-scored sets. For example, for the compound *rhinoceros horse*, the HF interpretation was "a horse that has a horn" while the LF interpretation was "a horse that has tough skin". To confirm a difference between the HF and LF interpretations a response time experiment was run. The difference between high and low frequency interpretations was reliable, $F(1, 20) = 5.845$, $p = 0.0253$.

Experiment 2

We define 3 context types - neutral, supportive and alternative. Supportive and alternative contexts make explicit reference to the relation between the head and modifier, while the neutral context makes no mention of the relation. The Supportive Context is defined as the condition where the paraphrase judgement question at the end of the story supports the interpretation suggested by the story. By contrast, the Alternative Context is the condition where the paraphrase judgement question supports an alternative question to the story i.e. if the story supports a HF interpretation then the question that follows will refer to the LF interpretation.

If out-of-context interpretations do not effect in-context processing then we would expect no difference between the

HF and LF conditions. If there is an influence then a difference in response time should be evident. This should be clearest in the Alternative condition where people move from one interpretation to another. If the independence view holds then it should take the same amount of time to go from HF to LF as it does to go from LF to HF, since their frequency of production out of context should not impact on processing time. This, however was not the case. We found a reliable difference between the high and low frequency interpretations, $F(1, 40) = 12.933$, $p < 0.001$, and also a reliable trend (using Page's L) showing that the supportive context was responded to most quickly followed by the neutral and then the alternative $L(12) = 158.5$, $p < 0.005$. The differences between the contexts is shown in Figure 1.

Figure 1: Mean RTs for HF / LF interpretations per context.

Discussion

We have shown here that in certain context types (alternative and neutral) out-of-context interpretations to have an effect on in-context processing. This shows that one aspect of out-of-context interpretations, namely their frequency of production, has an impact on the ease with which interpretations are comprehended in-context, which violates the basic assumption of the independence view.

Allocation of Attention in Neural Network Models of Categorization

Toshihiko Matsuka (tm249@columbia.edu)

James E. Corter (jec34@columbia.edu)

Department of Human Development, Teachers College, Columbia University, 525 W. 120th St., New York, NY 10027 USA

Arthur B. Markman (markman@psy.utexas.edu)

Department of Psychology, University of Texas, Austin, TX 78712 USA

We compared ALCOVE (Kruschke, 1992), RASHNL (Kruschke & Johansen, 1999), SUSTAIN (Love & Medin, 1998), and the Cortico-Hippocampal Model (CHM) (Gluck & Myers, 1993) to see how they account for selective attention in category learning. Such comparisons may usefully augment comparisons of the models' classification accuracy.

Method

We simulated the results of studies of classification learning by Medin and Schaffer (1978) and Medin, Edelson & Freko (1982). The parameter values used for each model were adjusted to minimize the SSE in reproducing the training classification responses by human subjects.

Attention allocation predictions for the models were derived as follows. ALCOVE and RASHNL have explicit attention weight parameters, which are reported below. For SUSTAIN, the dimension-specific tuning parameters, λ , are reported. In the CHM there are no explicitly defined dimension attention parameters. We defined implicit measures of a dimension's attentional salience, by summing the absolute values of weights from all input nodes associated with a given dimension to the hidden node layer in the hippocampal net component of the CHM. To enhance comparability among the models, we computed and report relative attention weights for all the models.

Summary of Results

For Experiment 2 of Medin and Schaffer (1978), all the models fit the training set classification probabilities roughly equally well, but RASHNL and SUSTAIN were somewhat more accurate in predicting classification responses for the transfer stimuli. In this stimulus structure Dimensions 1 and 3 are highly predictive of the binary classification task, and Dimension 4 is moderately predictive. Somewhat surprisingly, ALCOVE, RASHNL, and the CHM gave as much or more attention weight to Dimension 4 as to the more diagnostic dimensions.

For Experiment 4 of Medin, Altom, Edelson & Freko (1982), RASHNL and the CHM fit the training set classification probabilities best, but RASHNL was the best and the CHM worst in predicting the transfer classifications. In this stimulus structure, Dimensions 1 and 2 are diagnostic in the sense that each is highly correlated with the criterion classification response, but Dimensions 3 and 4 have a

simple XOR pattern in regards to the criterion classification. ALCOVE, RASHNL, and SUSTAIN all learn to allocate more attention to Dimensions 3 and 4, that together define the classification in terms of a simple XOR relationship. In contrast, the CHM pays more attention to the individually, but merely probabilistically, diagnostic Dimensions 1 and 2.

Conclusions

The four models give different predictions about attention weights for some stimulus structures. Examining and comparing these predictions may shed light on how the models learn. A promising line for future research is to gather direct data on how humans allocate attention in category learning (Matsuka, 2002).

How Goals Affect Evaluations of Animation Effectiveness

Julie Bauer Morrison (morrison@bryant.edu)

Department of Applied Psychology / Bryant College
1150 Douglas Pike / Smithfield, RI 02917-1284

Introduction

Animation commands our attention, it entertains us, but does it instruct us? Recent studies have shown animation is no more effective in instruction than comparable text or static graphics (for a review, see Tversky, Morrison, & Betrancourt, in press). This is particularly surprising because these studies often focus on teaching the kind of information that ought to be animation's strength, namely, change in time.

Despite the research to the contrary, the perception of animation is that it is an effective means of presenting information, specifically, information regarding movement. Why do these perceptions of animation differ from what research tells us of its effectiveness? The present research shows that the goals one has when evaluating different instructional media affect those evaluations, such that when we must learn from animation we judge effectiveness by our perception of what we have learned, whereas when we are simply evaluating animation we judge on aesthetics.

Media Comparisons

Method

Participants reviewed three learning interfaces, text, text plus static graphics, and text plus animated graphics, each displaying rules of movement through an environment. Thirty-one participants were under instructions to imagine they would be subsequently tested on the information (No Learning group), while 55 were to be tested (Learning group). Following the entire review process, participants rated each interface on three criteria using a 1-7 scale: how *effective* they thought the interface would be/was in helping them learn the material, how *confident* they would be/were about subsequent tests of the material, and how *enjoyable* it would be/was learning from the interface.

Results

For each rating criteria, effectiveness, confidence, and enjoyment, those in the No Learning group rated the interface with animated graphics the highest, followed by the ratings for the static graphics interface and the text interface (Effectiveness: $F(2,70)=16.1$, $p<.01$, Confidence: $F(2,70)=15.5$, $p<.01$, Enjoyment: $F(2,70)=21.6$, $p<.01$). All paired-sample t-tests showing the differences between the three interface types were significant at the $p<.001$ level (see Figure 1).

Participants in the Learning group showed a different pattern of results in which the ratings in the graphics conditions were indistinguishable. Despite there being overall differences for each rating across the three media

Figure 1: No Learning group ratings for effectiveness, confidence, and enjoyment.

(Effectiveness: $F(3,51)=15.1$, $p<.01$, Confidence: $F(3,51)=4.0$, $p<.05$, Enjoyment: $F(3,51)=3.2$, $p<.05$), the only t-test to reach significance was for the effectiveness rating comparing text and animated graphics (see Figure 2).

Figure 2: Learning group ratings for effectiveness, confidence, and enjoyment.

Subsequent analyses showed that the pattern of ratings for the Learning group mirrored actual performance. In other words, participants based their ratings on accurate judgments of learning, rather than on aesthetic elements of the interface.

Discussion

Judgments of different instructional media, in terms of their effectiveness, ability to inspire confidence, and enjoyability, differed based on the learner's goals. The attractiveness of animation, and, secondly, static graphics, influenced judgments of those who were not required to learn the information. Those who were required to learn made judgments that superceded the superficial aspects of the interface and focused instead on accurate perceptions of what had been learned.

A-Design

A-Design is a multi-agent computational system that automates the conceptual design process and is currently capable of solving several electromechanical design problems (Campbell, Cagan, & Kotovsky, 1999). A-Design takes input and output constraints for a desired electromechanical device and produces an array of conceptual designs that satisfy the problem constraints.

In order to solve a design problem, the system initially generates a population of candidate designs. These candidates are then evaluated along multiple dimensions, and all but the best candidates are eliminated before another iteration of design generation begins. In each iteration of the design process, the best designs from the previous iteration are modified and a number of new designs are also generated. This iterative design process is similar to the iterative design process employed by engineers solving design problems (Smith & Tjandra, 1998).

While A-Design's development was guided by some aspects of human cognition, it is not intended as a cognitive model of the design process. However, it does provide a point of departure for an investigation of the cognitive processes occurring in the field of engineering design. As an initial step in this investigation, modifications were made to A-Design in order to allow it to learn design knowledge during problem solving. A-Design was then tested to see if this learned knowledge could transfer to new design problems.

Learning from Design Experience

A-Design already had the ability to examine a group of designs and extract common subsets of electromechanical components that appear in every design of the group (Campbell, 2001). A set of interconnected components that appears in multiple designs will be referred to as a common subsystem of those designs. In this research, A-Design was said to have completed a design problem after it had run for a specified number of design iterations on that problem. Useful design knowledge was extracted after a problem had been solved by examining the best six designs produced in the final design iteration. Common subsystems were extracted from these designs, and these subsystems were added into a permanent memory store. Subsystems were indexed in this memory by the input and output constraints of the subsystem. A-Design could then add these

subsystems to designs that it generated while solving new design problems.

The declarative memory component of ACT-R (Anderson & Lebiere, 1998) was utilized to store these subsystems. The ACT-R model of memory provides the capability to retrieve a chunk based on information in any of its slots, which gives A-Design the capability of retrieving a subsystem based on only a subset of the information contained in the input and output constraints of the subsystem. The ACT-R system may also provide the basis for an expanded version of A-Design which will attempt to capture some of the cognitive processes underlying design.

Results

A-Design was tested on a number of design problems to see if knowledge learned in one problem could be transferred successfully both within and across problems. Results indicate that A-Design applies learned knowledge very successfully in the same design problem where the knowledge was learned, however there is very little successful knowledge transfer across problems. This lack of transfer highlights some aspects of representation and knowledge transfer that A-Design does not have but which human designers obviously do.

The Role of Exploration and Forward Checking in Human Scheduling

Stefani Nellen (Stefani.Nellen@urz.uni-heidelberg.de)
Joachim Funke (Joachim.Funke@psychologie.uni-heidelberg.de)
Department of Psychology, University of Heidelberg
Hauptstr. 47-51, 69117 Heidelberg, Germany

Research Objective: Connecting two strategies

We investigated how human participants work with the interactive Plan-A-Day (PAD) task (Funke & Krüger, 1993), which implements the task of scheduling numerous appointments during a fictitious day. We postulate that two strategies work together to enhance scheduling performance. The first strategy, remindful of instance based learning (cf. Logan, 1988) is to *explore* the feasibility of specific partial schedules by entering them into the PAD Interface. The second strategy, remindful of *forward checking* for Constraint Satisfaction Search (e.g. Russell & Norvig, 1995), checks in advance whether meeting an appointment would render another appointment impossible. In order to "verify" the results of forward checking, a certain amount of exploration is necessary, and in order to restrain exploration, forward checking is necessary. We conducted a study to determine which patterns of exploration are present in human scheduling and to validate our assumption that forward checking increases between two different PAD tasks.

Empirical results

The results reported in this section were obtained by presenting 43 student participants with two different PAD tasks (PAD 4 and PAD 5; a more detailed account of the analytic procedure can be found in Nellen, 2002).

Patterns of Exploration

The number of times participants modify their schedules during a PAD session is positively correlated with the number of complete restarts ("R"; abandoning a schedule completely and placing another appointment at the start), the number of different appointments placed at the start of a schedule ("Dif"), and negatively with the mean length ("ML") of the tried schedules. This pattern is consistent with exploration aimed at collecting a wide variety of experiences.

Table 1: Correlations between the number of schedule modifications and other process measures (explained in the text). Asterisks indicate significance at the level of $p < .01$ according to Fisher's Z test for correlations.

(N=43)	# of modifications	# of Modifications
	PAD 4	PAD 5
R	-.57***	-.461***
Dif	.74***	.665***
ML	.61***	.556***

Increase in forward checking

The amount of forward checking in the data was assessed by computing the percentage of "deliberate" modifications that are performed *before* participants are too late at an appointment, relative to the total number of modifications. Table 2 shows the considerable increase of forward checking between the two PAD tasks.

Table 2: Increase of the percentage of deliberate modifications (forward checking) between the two PAD tasks.

	Deliberate modifications	
	PAD 4	PAD 5
average	41.7 %	59.6 %
median	44.0 %	58.0 %
mode	0.0 %	100 %

Conclusion

Participants consistently explore the feasibility of partial schedules. However, they also acquire the skill of forward checking between two PAD tasks, resulting in an enhanced quality of the exploration, which now yields fewer dead ends. The quick and considerable increase of forward checking suggests a mechanism of skill acquisition as production composition as defined by Anderson (1987); while the continuous presence of exploration implies that the importance of specific experiences throughout the scheduling process.

Cognitive Functional Processing System: Reasoning about Quantitative Relationships

Kent L. Norman (kent_norman@lap.umd.edu)
Department of Psychology, University of Maryland
College Park, MD 20742-4411 USA

Introduction

How people acquire or generate rules for combining information for decision-making has long been of interest (Norman, 1974). A cognitive functional processing system is proposed which assesses the relationship between any two variables in the environment by taking the partial derivative of an assumed or known response surface for one variable (A) relative to another (B). The response surface is a general concept that can include stochastic and deterministic functions whether correlational or causal. The system is used to reason about the composition and decomposition of functions for combining information to make a single judgment. Brunswik's (1955) Lens Model, Norman Anderson's (1981), Information Integration Theory, and Kenneth Hammond's (1975) Social Judgment Theory are instances of such functions. In this system, decision makers store gradient functions in a matrix as shown in Table 1.

Table 1: Gradient Functions.

	A	B	C
A	--	$f(A,B)$	$f(A,C)$
B	$f(B,A)$	--	$f(C,A)$
C	$f(C,A)$	$f(C,B)$	--

$f(A,B) = +$ when increases in B lead to increases in A.
 $f(A,B) = 0$ when changes in B do not affect changes in A.
 $f(A,B) = -$ when increases in B lead to decreases in A.

When called upon to make subsequent judgments, decision makers generate composition rules from these gradients.

An experiment in which participants used a dynamic map query system to access information about geographic regions was used to investigate relationships learned and inferred between variables.

Experiment

Thirty undergraduates participated in an experiment in which they were asked to find states that satisfied one, two, and three variable range queries using a dynamic map query system (Dang, North, & Shneiderman, 2001). They adjusted sliders which continuously showed the dynamic set of states that met the search criteria.

Figure 1: Dynamic Query Interface.

The results showed that participants were able to code the existence and direction of the gradients between the criterion variables; that is, they were aware of the interrelationships of the search variables. A follow-up experiment was used to demonstrate the ability of the participants to generate new composition rules given the decomposed gradients they had stored from the queries.

Conclusion

The cognitive function processing systems accounts for how people are able to generate information integration rules in novel situations. They re-use previously stored gradients from other decision or search functions.

Strategies and eye movement of an expert in a video-game

Hidemi Ogasawara (hidemi@sccs.chukyo-u.ac.jp)

School of Computer and Cognitive Sciences, Chukyo University; 101 Tokodate, Kaidu-cho
Toyota, Aichi 470-0393 Japan

Takehiko Ohno (takehiko@bri.ntt.co.jp)

Communication Science Laboratories, NTT; 3-1 Morinosato, Wakamiya
Atsugi, Kanagawa 243-0198 Japan

Introduction

The purpose of this study is to explore human cognition in dynamic environment. Using a video-game, "Pac-man" (Fig.1), we have found the process of acquiring the expertise, which included the play strategy shift from a safer defensive strategy to a risky offensive one (Ogasawara & Ohno, 1999). These play strategies require different information acquisition strategies. To explore the relations between the play and information acquisition strategies, we examine again the player's eye movement data in Ohno & Ogasawara (1999).

Case

"Pac-man" is a game that a player controls Pac-man to eat dots while escaping from ghosts. If Pac-man eats one of four extra large dots (PPs), it becomes "strong" and can attack the ghosts for a limited time. The killed ghosts are transferred to the center of the screen and re-join the game. The game ends if the player cleared all dots on the screen or all Pac-men were lost. The game was implemented on Sun Sparc 10 with an eye mark recorder, NAC EMR-NC. One undergraduate student participated in this study. One session of the task usually included five games. The participant performed 24 sessions with one session in a day.

Result and Discussion

The sessions were divided into four periods (6 sessions/period) in the following analysis. The subject showed the similar play strategy shift as the previous subject (Ogasawara & Ohno, 1999) in the early periods of the 80 sessions. For the eye mark data, we examined the distance among Pac-man, the ghosts, and the eye mark. The result showed a tendency that the subject looked less around the Pac-man as he played more games.

Next we examined the details of the strategies and eye movement. One of the offensive strategies observed in the previous study was to move Pac-man to the center area after the consumption of PP. This strategy gives chances to kill ghosts twice: Pac-man can kill ghosts nearby, and after moving closer to the center it can kill once again the reappearing ghosts. But it is risky because Pac-man's

"strong" time might be expired on the way to the center. This strategy was also observed in this study. For example, for PP (LR) in the lower right corner this type of strategy was observed more frequently in the later session (from the 1st to the 4th period, 0%, 7.1%, 42.3%, 25.0% respectively). The four squares in Fig.1 show distributions of the player's eye marks in Pac-man's "strong" time after the consumption of the PP, from the 1st to the 4th period respectively. The eye marks are more concentrated around the PP and the center area as the periods progressed. The same tendency was observed for the other PPs.

Figure 1: Display for "Pac-man" and distribution of eye marks after consumption of PP(LR)

These results indicate that the play expertise in this case involves the acquisition of the play strategy of paying less attention on Pac-man and shifting it to the score-gaining but risky moves.

Not so Fast! (And not so Frugal): Rethinking the Recognition Heuristic

Daniel M. Oppenheimer (bigopp@psych.stanford.edu)

Department of Psychology, Stanford University
Building 420 – Jordan Hall, Stanford, CA 94305 USA

People face a lot of decisions and it stands to reason that we would want to expend as little cognitive effort as possible while still remaining accurate. Gerd Gigerenzer and his colleagues (1996; 1999) have contended that individuals have limited cognitive capacity, and are unable or unwilling to utilize complex statistical methods in decision making. Thus, individuals use heuristics in order to approximate “optimal” strategies more quickly, and at a much lower cognitive cost; hence the term “fast and frugal”.

The simplest of these heuristics is the recognition heuristic (RH) (Goldstein & Gigerenzer, 1999). Simply stated, RH claims that when making a judgment about two items, an individual who only recognizes one of the items will consider the known item to have a higher value. This is an important heuristic not only for its elegant simplicity, but also because it is the first step in a variety of other fast and frugal heuristics (Gigerenzer & Todd, 1999).

To test whether individuals actually use RH, Goldstein and Gigerenzer (1999) asked Americans to make population comparisons among pairs of cities taken from the 30 largest cities in Germany. Participants were also quizzed as to which cities they recognized. The researchers found that when a participant recognized only one city in a pair, he/she judged that city as larger about 90% of the time.

Goldstein and Gigerenzer (1999) clearly assert that the level of recognition is not important in using RH, “the distinction relevant for the recognition heuristic is that between unrecognized objects and everything else”. They discuss the “inconsequentiality of further knowledge” as an essential feature to maintain the frugality of the heuristic.

Accordingly, an individual using RH should judge a recognized city as larger than an unknown one *even if the recognized city is known to be small*. To test this, 50 participants were asked to judge populations of local cities that were known to be small, as compared to made-up cities (which, by virtue of being fictional, were unrecognizable).

Across all cities, only 37% of responses were consistent with RH. Thus, participants were significantly more likely to be inconsistent with RH than chance ($z = 4.25$, $df = 1$, $p < .05$). Results by city are summarized in table 1.

Table 1: Results of Experiment 1.

City	% using RH	City	% using RH
Cupertino	.30	Milpitas	.33
Sausalito	.20	Berkeley	.35
Foster City	.46	Freemont	.53
Total	.37		

One explanation for the discrepancy between these results and those of Gigerenzer & Goldstein (1999), might be found

in attributions of mental states. Individuals may recognize a city, and attempt to determine *why it is that they do so*. One reason for recognition might be size (large cities are more likely to be well known). However, when there is an alternate reason for recognition – in this case proximity – individuals may attribute their mental state to the alternative. That is, when there are reasons other than size that one might recognize a city, an individual may be less likely to use recognition as a cue that the city is large.

To test this, 172 participants were asked to make population estimates on cities which were famous for virtues other than their sizes (e.g. nuclear accident, featured in literature, etc.) as compared with made-up cities.

Slightly over 40% of the trials were consistent with RH. Subjects were significantly more likely to be inconsistent with RH than are summarized in table 2:

Table 2: Results of Experiment 2.

City	% using RH	City	% using RH
Los Alamos	.38	New Haven	.52
Chernobyl	.29	Timbuktu	.40
Nantucket	.36	Total	.40

This data suggests that although individuals do use recognition as a cue for size estimations, they do so in a more complicated manner than conjectured by Goldstein & Gigerenzer (1999). Individuals appear to make attributions about their mental state of recognition, and perform some kind of Bayesian discounting based upon that attribution. While it is beyond the scope of this abstract to discuss the mechanism thoroughly, it is clear that RH may not be as fast or frugal as it was originally postulated.

Neural Correlates of Perceptual/Semantic Encoding and Implicit/Explicit Retrieval: An fMRI Study

T. Park (tpark@chonnam.ac.kr)

Department of Psychology, Chonnam National University
Kwangju 500-757, Republic of Korea

The important distinction between implicit and explicit memory tests is based on intentional effort and conscious recollection experience during retrieval process (Schacter, 1987), which have been suggested to be associated with increased activity in prefrontal and medial temporal regions, respectively (Schacter & Buckner, 1998). The present study investigated brain areas activated during tasks involving implicit and explicit memory retrieval, and examined neural correlates of conscious recollection and intentional effort during memory retrieval.

Methods

Whole-brain functional MRI was used to examine 8 subjects during retrieval in a block-designed fMRI experiment (Fig. 1). Two incidental study conditions were manipulated: Semantic and perceptual word encoding conditions. This manipulation of level of processing (LoP) was expected to yield two retrieval conditions that differed with regard to intentional retrieval effort and successful conscious recollection: Semantic encoding yielding low level of retrieval effort with high level of retrieval success and perceptual encoding yielding high level of effort with low level of retrieval success. After studying, word fragment completion (WFC) task was presented and then cued recall (CR) task was presented with word fragment cues.

Fig. 1. A schematic illustration of study (above) and retrieval (below) paradigm. Critical study blocks (Semantic Encoding and Perceptual Encoding) were 30-s long separated by 30-s blocks of fixation (+). Critical retrieval blocks (Unstudied, Perceptually studied, Semantically studied) were also 30-s long separated by 30-s blocks of fixation in each of WFC and CR tasks.

Results

During explicit retrieval (CR) of the semantically encoded words, right inferior frontal regions (Brodmann Areas 45, 47) were activated but right anterior frontal regions (BA 10) were deactivated. These results suggest different roles of different prefrontal regions during explicit (episodic) memory retrieval: BA 45/47 involved in conscious recollection and BA 10 in intentional effort (McIntosh et al., 1997). Also, parahippocampal gyrus was activated during explicit retrieval of the semantically encoded words, and this result supports the idea that medial temporal lobe is a neural correlate of conscious retrieval success.

During implicit retrieval (WFC), occipital lobe (BA 17, 18 including fusiform gyrus) showed reduced activation when word fragments were primed, and this result supports the view that posterior areas are neural correlates of perceptual priming. Unexpectedly, right parahippocampal gyrus showed increased activation during implicit retrieval of the semantically encoded words. This result suggests that LoP effects which were often observed in studies of implicit memory retrieval could be the result of involuntary recollection (explicit contamination).

Mental Rotation Transfer

Philip Pavlik (ppavlik@andrew.cmu.edu) and John Anderson (ja@cmu.edu)

Carnegie Mellon University
Department of Psychology, 5000 Forbes Ave.
Pittsburgh, PA 15213 USA

The mechanisms underlying the effects of practice on mental rotation are still incompletely understood. Explanations that may apply include improved rotation processes (Wallace & Hofelich, 1992) and the learning of figure exemplars (Tarr & Pinker, 1989). One comparison of these two theories supported an exemplar explanation: Heil, Roesler, Link and Bajric (1998) looked for transfer of mental rotation performance in three conditions where 3-D block figure stimuli pairs were either identical to practiced pairs, the same objects around mixed old and new axes, or new objects around mixed axes. They found that mental rotation skill only transferred to the identical condition.

In contrast to this, in an experiment that included less practice and a transfer condition in which only the figure views were different, we found transfer of rotation performance.

There were two parts to the experiment. Participants trained for five blocks of 32 trials each, following which they tested in one mixed block for 128 trials. The four stimuli figures were identical to Shepard and Metzler (1971) and presented in pairs at four angular disparities: 0°, 40°, 80°, or 120°. Presentation was randomized and one-half of the trials were unanalyzed mirror-image foils.

Of the 128 test trials, 32 were identical to training, 32 involved the same axis of rotation but substantially new views on the same stimuli (at least a 90 degree oblique rotation), 32 involved the same view on the stimuli but an orthogonal axis of rotation (in this case the stimuli from the same/ same condition were simply presented rotated 90° around the Z), and 32 involved both an orthogonal axis of rotation and new views on the stimuli. This design allowed for a two by two (same vs different figures, same versus different axes) within-subjects comparison. Four between-subjects conditions of the experiment were run to counterbalance for possible effects of the stimuli set or the trained axis of rotation. Results for these counterbalanced conditions were not significantly different and were aggregated. 47 undergraduates participated of which 9 were discarded for failing to meet criterion performance.

Average millisecond per degree rotation speeds for each of the training blocks were calculated based on the assumption of a linear relationship of rotation latency and angular disparity. There were significant indications of learning indicating that participant RS's improved over training. In transfer participants showed a significant advantage to rotation around the same axis as training that did not depend on whether the figure views were the same or new. Mean times to judge 0° rotation pairs (intercept times) were significantly faster in the same-same condition than in any of the other conditions. See Table 1.

Table 1: Data Summary

	Train Blk. 1	Same/ Same	Same/ Orth.	New/ Same	New/ Orth.
Mean RS (ms/°)	18.8	15.2	16.3	13.3	17.2
0° (ms)	1830.5	1134.9	1345.3	1350.4	1327.7
40° (ms)	2800.5	1845.6	2242.7	2255.9	2345.4
80° (ms)	3314.3	2381.1	2949.4	2861.3	2972.4
120° (ms)	4164.7	2984.9	3280.8	2922.8	3410.6

Unlike the Heil, et al. (1998) study, our results suggest that transfer of rotation skill involving rotation around a particular axis can occur to new stimuli views. While we do not claim to refute Heil et al. (1998), it does seem that non-stimulus-specific transfer can occur. On the other hand the special advantage for 0° rotation pairs that were repeated from training does suggest that there is also a stimulus-specific component to the learning. The fact that the new view/same axis transfer condition showed transfer of RS, yet showed no benefit in the 0° disparity (identity recognition) trials suggests that our new view stimuli condition was significantly unique and transfer of rotation skill to these new views depended on general rotation learning independent of any exemplar view strengthening. As revealed by the data and a subsequently formulated ACT-R model, there is a complex variety of learning that is taking place in the first 200 trials of a mental rotation experiment.

This study approached the language and the thought under the cognitive perspective. We investigated the interaction, dependence, or independence of these cognitive processes, but above all J. Fodor's inatist presupposition of a "language of the thought." Such presupposition transcends the specific subject of the language and of the thought. Fodor (1975) affirms that it would exist in the human brain a structure that would take us to develop a formal system of linguistic registrations that would incorporate all of the universal properties of the language. This "language" would be the communication between the mental states and the structures of the thought. Therefore, it would allow us to do hypotheses regarding the knowledge that we want to acquire, and, still, to classify, and to classify it. This way, we elaborated an experimental situation in which we showed that children from 6 to 7 years (in the first school stage), are not capable to acquire real new concepts not belonging to the immediate universe of knowledge. In general terms, our results point that after the contextualization is notable the index of understanding of the new concept for the children. Although this concept is distant of their cognitive universe, it is significant for them, because they are part of real events of their lives. Partly, we corroborated the theory of Fodor that we acquired new concepts starting from the formulation of hypotheses. However, unlike Fodor that affirms that the innate mental structures are responsible for the acquisition of new concepts, Jean Piaget sustains that such concepts are acquired through the individual's interaction with the middle in that he is always not having any innate determinant. In this case, the categorization of new concepts involved a mental representation purely abstract, as foresaw Fodor, however, sustaining bonds cultural, historical and social in the understanding and apprehension of the new concepts, as announced Piaget. We believed that the results demonstrate that the contextualization of the new concept in the children's cognitive universe is the first step for a significant learning.

Mental representation in mathematical problem resolution

In this paper we investigate mental-representation strategies applied to solve contextual problems that involve mathematical calculus. We are interested in formal procedures, algorithms, and strategies that could be used by three groups of peoples: with specific mathematical knowledge (*the expert group*); without this knowledge (*the control group*); and without this specific knowledge but acquainted with the designed problem context (*the familiar group*).

Our investigation demonstrates that the reasoning developments of these three groups are quite different from one another: in the expert group the reasoning is only based on algorithmic operations; in the control group the reasoning combines algorithm with other mathematical strategies; and the familiar group uses a more intuitive reasoning, probably influenced by their familiarity with the problem context and by their special mental strategies.

In this research we aim to come through with Cognitive Science studies on the nature of human knowledge. Mathematical problem resolutions in general and arithmetic calculus in particular are very interesting tools to recognize the difference between expert and novice knowledge and reasoning.

Browsing Multiple Texts under Time Pressure

William R. Reader (readerwr@cardiff.ac.uk)

Stephen J. Payne (paynes@cardiff.ac.uk)

School of Psychology, Cardiff University
Cardiff CF10 3YG, UK

The Problem of Multiple Texts

With the expansion of the World Wide Web and other electronic information sources, it is becoming increasingly important for learners to actively allocate their time among texts in order to maximize their learning. Finding relevant texts is no longer the main problem; rather the problem is one of adaptive time allocation among multiple relevant texts. What constitutes a good text is dependent on, among other things, the individual's background knowledge, since comprehension requires textual information to be integrated with this knowledge so as to construct a situation model. If there is too much overlap between the text and the reader's background knowledge, then the text affords little opportunity for learning, but if there is too little overlap then the text would be incomprehensible. Good texts for learning therefore fall in the middle ground that Wolfe, Schreiner, Rehder, Laham, Foltz, Kintsch & Landauer (1998) call the zone of learnability.

Thus, at least one task facing the self-directed learner is to allocate his or her time selectively to texts that fall within this zone of learnability and ignore the rest. Experimental studies of metacognition (e.g. Son & Metcalfe, 2000) have explored the way in which prior judgments of text difficulty influence study-time allocation, but have been silent about our main question, which concerns the strategies by which difficulty judgements are integrated with browsing to produce preferential study. To understand these browsing strategies we follow Pirolli & Card (see 1999) in drawing on optimal foraging theory (see Stephens & Krebs, 1986).

Foraging Theory and Browsing

One of the findings in the optimal foraging literature that is particularly relevant to the issue of selective browsing is that animals will *sample* unfamiliar food patches in order to decide which to exploit. Krebs, Kacelnik & Taylor (1978) observed that great tits initially switched rapidly between two food patches before settling down to exploit the higher-value patch.

Do readers use a similar sampling strategy when deciding how to allocate their time among multiple texts? Sampling strategies have as an objective to choose the best source (of food or information). An alternative to such the sampling strategy is a satisficing strategy, in which readers continue to read any text that is good enough (which we take to mean that the text would still fall within the zone of proximal learning).

Experiments and Findings

We have conducted a number of experiments on reading multiple texts under time pressure, investigating the prevalence of sampling and satisficing strategies and the effectiveness of these strategies for the preferential allocation of time among texts.

The results of Experiment 1 suggested that readers were adaptive in that more expert readers allocated more time to more difficult texts, and that satisficing was a much more common strategy than sampling. The results of Experiment 2 suggested that the provision of outline overviews led to participants being more selective in the documents that they read, and encouraged sampling to the extent that it became the modal strategy. Other experiments have confirmed the general adaptive character of browsing and shown how document preference is influenced by the nature of the learning task (e.g. studying to answer factual questions leads to a preference for more difficult texts than does studying to write a general essay).

Acknowledgments

Color Palettes for Displays: Optimization by Genetic Algorithm

John Rehling (rehling@cs.cmu.com)

Human-Computer Interaction Institute
School of Computer Science
Carnegie Mellon University
5000 Forbes Avenue
Pittsburgh, PA 15213 USA

Introduction

The use of color can make computer displays and interfaces more readable. Ideally, the colors in a display will be maximally different from one another. For small values of n , it is not difficult to choose instinctively colors that are clearly distinct from one another. For larger n , however, it becomes more difficult to assure that the colors are immediately distinguishable from one another. A genetic algorithm can be used to pick large sets of colors such that all pairs in the set are, according to one metric, nearly maximally distinguishable. Even allowing for imperfections in the scheme, these sets are in practical terms very easily distinguishable, and could be of use to designers.

The approach

The metric used for the differentiability between two colors is the CIE 1976 $L^*U^*V^*$ color space CIE. A genetic algorithm was used to find sets of colors that optimized a fitness function based on the CIE metric. With n as the number of colors being explored in a given run, an individual consisted of $3n$ values, represented as real numbers from 0 to 255, which is a twist from most GAs, which use strings of Boolean bits to represent individuals. The mutation operator, traditionally the toggling of a bit when bitstrings are the basis of the representation, is instead the alteration of a 0-255 value by adding to it a random number with a distribution with tails that ranged from -100 and 100 (but clustered tightly near the mode of zero).

In each generation, the population would consist of the ten individuals rated highest by the fitness function, plus 45 copies of those individuals pass through the mutation operator, plus five new, random individuals. There was no breeding of individuals, since a set of colors is satisfactory only as a function of the whole set; except when n is very small, the cleaving together of two partial solutions is exceptionally unlikely to yield a good solution.

After some trial and error, a fitness function was derived that consisted of the CIE distance between two closest (i.e., least-easily distinguishable) pair of colors in the set plus a small constant (0.00001) times

the sum of CIE distances between all pairs of colors in the set. This makes the first priority that no two colors in the set are very much alike; as a secondary priority, it also tries to maximize other separations between color pairs given that the worst pair has been dealt with.

The genetic algorithm was run to find sets of colors for values of n from 2 to 12. In one set of runs, the colors were constrained only by what could appear on a typical computer monitor. In other sets of runs, it was required that black, white, or both black and white be included in the set of colors. Runs lasted until they appeared to converge upon a best value. At least three runs were conducted for each situation, with the best of all runs reported below.

Results

The printed form of the Proceedings is not the ideal medium for the presentation of the color palettes that the GA generated. The palettes are described here in terms of the R3 colors that most closely match the RGBs produced by the output. In many cases, the program produced values that differed slightly from any named color, although the differences from those listed below are almost always imperceptible.

Unconstrained: $n=2$ {lime, magenta}; $n=3$ {red, lime, blue}; $n=4$ {red, yellow, aqua, magenta}; $n=5$ {deepPink, orange, lime, aqua, deepViolet}; $n=6$ {black, red, deepPink, orange, lime, blue}

White plus: $n=1$ {red}; $n=2$ {red, lime}; $n=3$ {red, lime, blue}; $n=4$ {red, lime, teal, magenta}

Black plus: $n=1$ {red}; $n=2$ {red, blue}; $n=3$ {red, lime, magenta}; $n=4$ {darkOrange, limeGreen, blue, magenta}

Black, white plus: $n=1$ {red}; $n=2$ {red, lime}; $n=3$ {red, lime, blue}; $n=4$ {red, lime, blue, magenta}

Letter Spirit: An Architecture for Creativity

John Rehling (rehling@cs.cmu.com)

Human-Computer Interaction Institute
School of Computer Science
Carnegie Mellon University
5000 Forbes Avenue
Pittsburgh, PA 15213 USA

Introduction

The Letter Spirit program is a model of human creativity in the domain of typeface design. The task of Letter Spirit is to take as input a few gridletters, letters rendered on a medium-resolution grid, that are intended to represent the same style. Using those seeds as a beginning, Letter Spirit creates versions of the remaining lowercase letters of the roman alphabet until it has completed an entire *gridfont* of 26 stylistically consistent gridletters.

Approach

Letter Spirit consists of three modules, each being a relatively complex program solving a vital subtask of gridfont design. The three modules are all based upon an architecture common to the cognitive models implemented by the Fluid Analogies Research Group. Most of those projects, including Copycat (Mitchell, 1993), Tabletop (French, 1992), and Metcat (Marshall, 1999) aimed at implementing increasingly refined models of analogy. One of the Letter Spirit modules (McGraw, 1995) pursues a similar approach, although its task is gridletter categorization rather than analogy.

The Letter Spirit program has a top-level loop that coordinates the three modules into a single strategy of design called *review-and-revision*. The program has one module, the Examiner, that detects letter category, while the Adjudicator evaluates style, and the Drafter, which creates new gridletters that aim to represent a goal letter category and that style.

To get around the brittleness that afflicts many AI models, Letter Spirit hands the Drafter's output to the other modules and they rate each gridletter for how well it fits its intended letter category and the intended style, respectively.

The design phase of a Letter Spirit run thus amounts to the execution of a loop, in which a letter category is selected and then the Drafter renders a gridletter that, ideally, incorporates the goal style as well as that letter. The Drafter's attempt is run past the Examiner and the Adjudicator, and if the attempt is the best version thus far for that category, as determined by the scores that the Examiner and the Adjudicator generate, then it is kept as the current version of that category in the gridfont. This loop runs many times, and as it does so, the quality of the gridfont should incrementally increase.

Results

Figure 1 shows five gridfonts that resulted from runs that each began with the program receiving five gridletters (in each case, 'b', 'c', 'e', 'f', and 'g') as input.

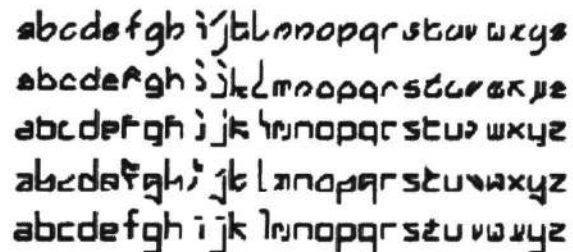

Figure 1: Five Letter Spirit-designed gridfonts.

While the Letter Spirit program captures human creativity, at best, partially, it is our belief that the model captures many essential aspects of human creativity. Perhaps more important, we argue, is the opportunity that the output provides to identify shortcomings in the current approach so that future models of creativity can converge more closely upon human creativity (Rehling, 2000). More detail is at www.cogsci.indiana.edu/farg/rehling/lspirit/thesis

How to Make a Computer Conscious

Alexei V. Samsonovich (asamsono@gmu.edu)

Krasnow Institute for Advanced Study, George Mason University
4400 University Dr. MS 2A1, Fairfax, VA 22030-444 USA

Introduction

Why do computers lack common sense initiative? What is so special about human brain and consciousness that computers still cannot reproduce? Much brain information processing deals with abstract representations of agents, such as instances of the self and others. Therefore, implementing the right sense of agency in a computer could provide a solution. Here I outline a general approach to the problem of a computer-based implementation of the mind.

Basic Formalism

This approach is based on the formalism of schemas. The notion of a schema used here is more general than any notion of a schema used, e.g., in psychology, or in computer science, or in social sciences. Examples of schemas range from very abstract notions (a thing, an entity, an event, a property, a relation, an agent, an act of learning a schema), to very concrete things (an apple, minus one, red, grasping a pen with the right hand, etc.). In this framework schemas can represent any cognizable thing, including qualia, thoughts, intentions, feelings, and so on. A predicate, a variable, a quantifier, an instruction or even an analog signal can be represented in terms of schemas as well. Elements and components of schemas, as well as complexes made of schemas, can be viewed as schemas on their own. Generally, a schema can be characterized as an abstract model, a template or a prototype that can be bound to a particular content. Definitions of particular schemas must specify semantics, syntax, pragmatics and dynamics. Schemas can be represented in a computer symbolically in a standardized format with the structure of a nested list.

When an instance of a schema is bound to a particular content, it forms a state. Schemas and states are dynamical objects in this framework. They evolve in time according to rules defined by schemas. E.g., states can be initiated, executed and terminated; dynamics of a state may affect other states and schemas. A chart is a special state that represents a mental perspective of an agent (e.g., I-Now, I-Yesterday, He-Imagined). When a state is bound to a chart, it represents a mental state. Perspectives change with time according to the flow of the subjective time: I-Now becomes I-Previous, and so on. In addition to perspectives, charts have internal dimensions that determine attitudes of the associated states: e.g., I-Now may contain a belief about a past or a future. The general idea of this framework based on schemas is not new; however, its known analogs (e.g., OPS, SOAR, ACT-R) lack generality and do not implement a proper concept of the self possessing free will.

Implementing Free Will and The Self

Charts labeled "I-..." represent instances of the self of the virtual individual, including cognitive and metacognitive perspectives. Other charts may represent mental simulations of "third persons": in other words, a "theory of mind". Only the content of I-Now represents the current content of consciousness in this framework. Mental states in I-Now have special privileges: e.g., they can directly determine scheduling of voluntary acts and may access all other charts.

A distinguishing feature of this framework is that it is based on the fundamental properties of the human self (*error fundamentalis*: Nadel & Samsonovich, 2002), including its uniqueness, its localization in a particular context, its indivisibility, its self-consistency over time, and finally, its apparent free will and self-awareness that are present in the contents of consciousness at any instance.

These properties are introduced via the design of the system or via dynamical constraints. They guarantee certain degree of coherence in system's behavior. Their products are the emergence and the maintenance of a unique working scenario (i.e., a consistent sequence of charts leading from I-Now to I-Goal) and the generation of voluntary actions. An action is considered voluntary, iff it results from an intention of "I" (represented by a mental state in I-Now), is consistent with the working scenario and is not biased by any additional factor. Intentions are selected among the available ideas based on their fitness into the working scenario, and ideas (i.e., mental states in I-Now that represent feasible actions) result from the activity of states.

Previously active charts may disappear with time together with their contents – or be remembered, thus contributing to the episodic memory and/or to the system of values, i.e., the memory of dreams and goals. In contrast, the semantic memory is represented by the set of schemas. Creation of new schemas is controlled by the learning schemas and may be supervised or not. A complete system should be able to work interactively with a human instructor, using a specially designed language. The range of interaction paradigms may include listening to and completing stories, learning how to play or playing games, learning languages or scientific disciplines, operating a robot in a virtual environment, simulating virtual characters, designing or training other systems of the same kind, etc. Primary applications of this framework should relate to natural language understanding.

The Role of Prior Beliefs in Processing Analogical Arguments

Lelyn Saner (les53@pitt.edu) Christian D. Schunn (schunn@pitt.edu)

Introduction

How is the background opinion of the person who is processing an analogy related to that person's evaluation of the analogy, both in terms of how the analogy is mapped to form a conclusion and in terms of the conclusion itself? Assuming that people have pre-existing perceptions of the analogs referred to, will they be more or less likely to reflect on and evaluate the analogy?

Several researchers have examined the degree to which the process of mapping between source and target analogs is influenced by the context in which it is done (Blanchette & Dunbar, 1997; Dunbar & Baker, 1994; Holyoak, 1985), including the type of problems, situations, or issues that are being compared, the environment in which the comparison is being made, and the goals or reasons that a person has for engaging in the mapping process. We explored the possibility that the attitudes that people have associated with the analogs prior to the presentation of the analogy might influence the way people respond to the analogy.

Methods

We elected to conduct this study over the Internet in order to get a broader, more representative sample of perspectives on the analogs, and participants were recruited primarily through Usenet newsgroups, where discussions and debates on various topics occur on a continuous basis. Two controversial socio-political issues, Abortion and Gun Control, were selected as target analogs for this study. Two novel source domains were selected for each of the two target domains such that they could be mapped to argue either for or against the key issue in the target domains.

Participants read a general introduction to the experiment on the first page of the website and were then asked for some demographic information. After completing a 14-item background opinion questionnaire to measure their opinions on the target issues, each participant performed two analogy-processing tasks, which instructed them to read a scenario that related one of the issues to one of its two analogs, and then to write a response to the scenario.

Each scenario argued for either a Pro- stance on the issue (Pro-Abortion or Pro-Gun Control) or an Anti- stance (Anti-Abortion or Anti-Gun Control). With the participants' actual background opinions on the issues and the record of which scenario that participant received for each issue, we determined if, for each issue, they received the statement supporting the same stance on that issue as their own.

Participants were also asked, immediately after reading the scenario, to rate their level of agreement with it.

Responses were classified according to whether or not the analogy was processed in the response. Those that either presented an argument for a position that did not include any analogy at all or described their opinion on the issue only, without employing any argument, were coded as not processing the analogy. Three indicators were used to code a response as processing the analogy; (1) explicitly discounting the validity of the analogy presented in the scenario, (2) building upon the presented analogy in the response, or (3) choosing new analogies for the issue in favor of the one presented. Between two raters, using Cohen's Kappa as the measure of reliability, the agreement in classification of the responses was relatively high ($\kappa=0.86$, $n=50$).

Results

We observed that the likelihood of processing the analogy in a response was related to the average level of overall agreement with the scenario that was read. As the level of agreement with a particular scenario increased, so did the proportion of people who processed the analogy. At the same time, contrary to our expectations, there was no significant relationship, for either issue, between participants' background opinions on the issues and the likelihood of processing. On the basis of the first result, however, we concluded that there is evidence that peoples' opinions influence how they process analogies. We suspect that background opinion is one component of agreement with the scenario and that further exploration may reveal how it contributes to the way people process analogies.

A Pyramid Model of the Perception of Partially Visible Figures

Michael R. Scheessele (mscheesse@iusb.edu)

Department of Computer & Information Sciences, Indiana University - South Bend
1700 Mishawaka Ave., South Bend, IN 46634 USA

Zygmunt Pizlo (pizlo@psych.purdue.edu)

Introduction

Frequently, figures in our visual field are only partially visible. One figure may partially occlude another, for example, or a particular figure may appear **fragmented** due either to camouflage or to low contrast between it and the background. Despite such challenges, the human visual system routinely perceives figures that may only be partially visible.

One prior theory of the perception of partially occluded figures (Nakayama, Shimojo, & Silverman, 1989) states that contours "intrinsic" to a figure of interest must be distinguished from those "extrinsic" to it and that this classification requires depth cues. Our theory proposes that the human visual system can use a *variety of cues, local or global*, to perform this classification and that this classification serves as the basis for perception of both partially occluded *and* fragmented figures. Further, we propose that an exponential pyramid, from the machine vision literature, provides a good model of how the human visual system implements this classification.

Exponential Pyramid Model Description

The Exponential Pyramid has been proposed as an adequate model of the human visual system (Rosenfeld, 1990; Pizlo, Salach-Golyska, & Rosenfeld, 1997). Our model uses a "non-overlapped quad-pyramid". Assume that the bottom layer of the pyramid has n processing nodes. The next layer has $n/4$ nodes, the one above that $n/16$ nodes, and so on. The top layer has only one node. Each node in a layer connects with four distinct 'child' nodes in the immediately lower layer and one 'parent' node in the immediately higher layer. Such a pyramid has $(\log_4 n) + 1$ layers. Each node in the pyramid has limited memory and processing capability. An image is input to the bottom layer (Jolion & Rosenfeld, 1994). The image may also be represented at each higher layer (with increasing spatial scale or 'receptive field size').

Our model features a bottom-up processing stage followed by a top-down stage. In the bottom-up stage, local variance of various contour features (e.g., orientation, length) is computed. When the variance of a contour feature abruptly changes between successively higher layers, the presence and position of a figure in the image is indicated (i.e., the figure 'comes into view'). In the top-down stage, the statistical information computed in the bottom-up stage is used to classify image contours as either intrinsic or

extrinsic to the target figure. The model has only one free parameter: the standard deviation of decisional noise. Model and human performance were compared across 11 experimental conditions.

Method

In each trial of the **human psychophysical experiments**, a polygonal figure was partially occluded by simple shapes – diamonds (Exp. 1, two conditions) and squares (Exp. 2, nine conditions). A subject's task was to respond whether the figure was presented in its upright or rotated (180°) position. Contours of occluders differed from those of the figure in terms of orientation (Exp. 1) and length (Exp. 2). Depth cues from occluders were minimal. **Model simulations** were run for all 11 conditions using the same sets of stimuli as those used by the human subjects.

Results

Subjects used orientation (Exp. 1) and length (Exp. 2) differences between the contours of a target figure and those of occluders, in detecting the figure. Model simulations accounted well for human performance in the 11 conditions of Experiments 1 and 2.

Conclusions

The human visual system can detect and use a variety of cues, local or global, to classify contours as either intrinsic or extrinsic to a partially visible figure. Our exponential pyramid-based computer model provides a good account of how the human visual system implements this process.

The goal of the DARPA Augmented Cognition program is to extend, by an order-of-magnitude or more, the information management capacity of the "human-computer" interaction by developing and demonstrating enhancements to human cognitive ability in diverse and stressful operational environments. Specifically, in its current phase, the program is focused on development of the technologies needed to measure and track a subject's cognitive state in real-time - these include functional near infrared imaging (fNIR) devices, as well as single site electroencephalographic (EEG) recordings. Through measurement and understanding of cognitive state in real-time, the ultimate goal of cognitively aware computational systems is within reach. Military operators are often placed in complex human-machine interactive environments that have been shown to fail when a stressful situation is encountered. The technologies under development in the Augmented Cognition program have the potential to enhance operational capability, support reduction in the numbers of persons required to perform current functions, and improve human performance in cognitively challenging environments.

Learning by Collaborating Revisited: Individualistic vs. Convergent Understanding

Hajime Shirouzu & Naomi Miyake (shirouzu, nmiyake@scs.chukyo-u.ac.jp)

School of Computer and Cognitive Sciences, Chukyo University

101 Tokodachi, Kaizu-cho, Toyota, 470-0393 Japan

Introduction

Roschelle (1992) characterized the process of "learning by collaborating" as a search of convergence among members. This paper makes a contrasting claim that each member is individualistic in how s/he interprets the learning task, how s/he solves it, and what kind of understanding s/he gains from collaboration. The others serve as a "monitor" (Miyake, 1986) to observe what the member is doing from a slightly broader perspective and to check its validity, which triggers the member's re-interpretation. This leads a learning pair to an iterative chain of re-interpretations, not to a search of the common ground among the two, which are often exchanged by verbal expressions in collaborative situations. In this paper we re-analyzed protocol data of collaborative learning processes in Roschelle (1992) and Shirouzu, Miyake & Masukawa (2002) to show that members' verbalizations reflecting their interpretations or re-interpretations are individualistic through the processes.

Re-analyses

Roschelle (1992)

Two students, Carol and Dana, elaborated their conceptions of velocity and acceleration using a computer simulation of a Newtonian micro-world. As Roschelle pointed out, they gradually revised and refined their verbal "metaphors" to mean these notions. A closer look at their protocol reveals, however, that the two did not seem to converge on the usage of particular metaphors to mean particular things. Dana started with a geometric "lengthen (addition)" metaphor to indicate the velocity vectors, the acceleration ones or their relations. Carol heavily used a "pull" metaphor to represent the dynamic relations between these factors. Carol finally verbalized an expression of "travel along" in the last episode, Episode 5, to explain the composition of velocity and acceleration, which Roschelle interpreted as an integration of the two metaphors, "lengthen" and "pull" one. Dana, however, did not use the verb "pull" other than in Episode 1, while Carol superimposed her metaphor to paraphrase Dana's insight into additive nature of vectors in Episode 3 (she said "right that's what I'm saying" to Dana without any specification of "what"). Besides, Dana did not share the expression "travel along" during training sessions and used "move along" in their post-training interview. They thus independently revised their verbal expressions. There might be two independent shifting processes of understanding.

Shirouzu, Miyake & Masukawa (2002)

When paired subjects were asked to indicate $2/3$ of $3/4$ of the area of a square sheet of paper, they shifted their strategies from the non-mathematical one in the first trials to

the mathematical one in the second trials than solo subjects. Seven out of nine shifting pairs gradually generated the variations of solutions, from the most externally oriented two-step solution (making $2/3$ out of the $3/4$) to the external-internal mixed one (reinterpreting the externalized answer as one-half) to the most abstract one ($2/3 \times 3/4 = 1/2$). Shirouzu et al. found that, though the members shared the algorithmic view of the task at the end of the first trial, the member who verbalized such a view during the first trial tended to propose the abstract solution in the second trial. Shirouzu (2001) also used a similar task in a small-case learning experiment with six 6th grades only to find individual differences in the quality of their reports of six months later depending on their verbalization during the experiment.

Discussion

Under seemingly "one voice" in the collaborative situations, there were different courses or levels of understandings of the members, which were reflected by their particular language use (methodologically, the transfer task or the post interview--especially individually conducted one--reveals differences well). Roschelle thinks much of convergence because it warrants not only shared understanding between members but also their integration of scientific concepts. However, we can assume another, more real course of knowledge integration, in which each member gradually revises their interpretation of the task or the solution processes using the other's monitoring as stepping stones. Shirouzu et al. showed that the shift between solution variations coincided with members' role shifts between task doing and monitoring. Carol and Dana often proposed "what if" cases to each other to monitor their understanding. This series of re-interpretations enables the interactive and gradual integration of the solution variations of different abstraction levels. Careful analyses on the language use in collaboration makes us possible to feed a better folk-model of collaborative learning back to everyday learners (also see Miyake & Shirouzu, 2002 in this conference).

Retrieval Effects on Confidence in General Knowledge

Winston R. Sieck (sieck.3@osu.edu)

Department of Psychology, The Ohio State University
1827 Neil Ave, Columbus, OH 43210 USA

J. Frank Yates (jfyates@umich.edu)

Department of Psychology, The University of Michigan
525 E University Ave, Ann Arbor, MI 48109 USA

At a recent panel discussion sponsored by the Ohio Board of Education, credential-laden fellows of the Discovery Institute argued with absolute conviction that the Darwinian theory of evolution is flawed, and that we must have been created by intelligent design.

What underlies the confidence we have in our beliefs and knowledge? A typical assumption underlying many models of confidence in general world knowledge is that assessments of arguments that favor or oppose chosen answers will primarily, if not exclusively, determine confidence in choice (e.g. Griffin & Tversky, 1992; Koriat, Lichtenstein, & Fischhoff, 1980; also see Allwood & Granhag, 1996). Differences between models largely reflect distinct proposals for how evidence assessment is accomplished, and the extent and manner of bias that is postulated to exist in the process. For example, Koriat et al. (1980) suggested that memory search produces reasons for and against presented alternatives, and that assessment is biased in that choice-consistent reasons are relied upon more heavily than choice-inconsistent reasons.

The current study tests the hypothesis that confidence also depends in part on successful retrieval of topical information that is not directly relevant towards arriving at a choice. Successful retrieval of facts about the general topic is used as evidence that one is knowledgeable about the subject area, and thus likely to be reasoning correctly.

Method

Participants ($n=159$) were presented with a series of questions following the form: "Which species has a longer gestation period: (a) chimpanzees, or (b) humans?" Participants first chose one of the two alternatives as more likely to be correct, and then specified a probability between 50% and 100% that their choice was, in fact, correct. Subjects in a *reasons* condition were asked to write all possible reasons for and against each alternative answer, prior to choosing. Participants in a *recall* condition were asked to recall all of the facts they could about the topic of each question before choosing. *Control* condition participants simply answered the questions with standard, non-directive instructions.

Results

The principal results are shown in Table 1. Mean confidence, proportion correct, and overconfidence were

virtually equivalent across conditions. Accuracy discrimination (mean confidence given correct – mean confidence given incorrect) was larger for recall than the other two conditions. Also, the correlation between confidence level and choice accuracy was larger for recall than the other conditions.

Table 1: Confidence/Correct Indices by Condition.

Indices	Control	Reasons	Recall
Mean Conf.	.73	.72	.72
Prop. Correct	.66	.66	.66
Accuracy	.04	.05	.10
Discrimination			
Pearson's r	.12	.16	.29

Discussion

Writing all possible reasons for and against alternatives had no impact on choice or confidence. Writing all facts that could be recalled about the topic of each question resulted in confidence judgments that better discriminated between correct and incorrect answers, as compared with control and reasons conditions. Preliminary results from coding of the listed reasons and recollections (not shown), indicate that approximately the same amounts of information were generated under the two procedures, but that important qualitative differences in the protocols seem to exist. It appears that successful recall of facts that are relevant to the topic, but that do not constitute reasons for or against presented alternatives, is taken as critical evidence that chosen alternatives are correct.

Perception matters: Effects of perceptual richness on categorization

Vladimir M. Sloutsky (sloutsky.1@osu.edu)

Center for Cognitive Science

Ohio State University, 208b Ohio Stadium East, Columbus, OH 43210, USA

Anna V. Fisher (fisher.449@osu.edu)

Center for Cognitive Science

Ohio State University, 208b Ohio Stadium East, Columbus, OH 43210, USA

Abstract

Research presented here examines effects of perceptual and non-perceptual information on categorization as a function of perceptual properties of presented information. In Experiment 1, triads of perceptually-rich and perceptually impoverished stimuli were calibrated to equate discriminability of both kinds of stimuli. In Experiment 2, participants were presented with categorization task under two conditions, one, in which stimuli were not labeled and another, in which linguistic labels were provided. In the first condition, participants relied solely on perceptual information, and there was no difference between perceptually-rich and perceptually-impoverished stimuli. However, in the second condition, where linguistic labels were provided, there were dramatic differences across different stimuli types: perceptually-impoverished stimuli elicited mostly label-based responses, whereas perceptually-rich stimuli elicited mostly perceptually-based responses.

Introduction

It has been often argued that similarity is an insufficiently constrained rule to guide categorization decisions and that there is often a dissociation between similarity and categorization. For example, Rips (1989) presented participants with stories about animals undergoing appearance transformation. Participants were asked to rate similarity of the transformed organism, and to determine its category. While they judged the transformed animal to be more similar to the new category, they considered the transformed animal to be more likely a member of the old category (i.e., reptile). However, there is evidence (Johnson & Mervis, 1997; Sloutsky, Lo, & Fisher, 2001) perceptual information plays an important role in categorization. Therefore, one might counter argue that the transformational studies used only verbal descriptions or perceptually-impoverished pictures to demonstrate that perceptual similarity is of secondary (if any) importance for categorization. At the same time, it is possible that the role of perception is not fixed, such that contribution of perceptual information to categorization varies with variance in perceptual richness of presented information. This possibility was addressed in the present research.

Experiment: Categorization and perceptual richness

A total of 125 undergraduate students took part in the experiment. The experiment had a 3 (stimuli type: Perceptually-rich vs. Perceptually-impoverished) by 2

(Labeling condition: Label vs. No-Label) by 2 (similarity ratio: Test items are equally similar to the Target vs. Test A is more similar than Test B to the Target) mixed design with stimuli type and labeling conditions as between-subject variables and similarity ratio as a within-subject variable. In the label condition, pictures were accompanied with artificial two-syllable linguistic labels that were presented as count nouns (e.g., a bala, a gula). Participants were presented with triads of stimuli and asked to select from the two bottom pictures (i.e. Test A and Test B) the one that was the same kind of animal as the upper picture in the center (i.e. the Target).

Proportions of categorization choices were subjected to a three-way (Stimuli Type by Labeling condition by Similarity ratio) mixed ANOVA. As expected there was a significant stimuli type by labeling interaction, $F(1,119) = 4.08$, $MSE = 0.11$, $p < .05$, indicating that there were no differences among stimuli types in the no label condition, while there were significant differences in the label condition. This interaction is the most critical as it indicates that differences in the label condition do not stem from different discriminability of perceptually-rich and perceptually-impoverished stimuli. The results clearly indicate that reliance on perceptual and non-perceptual information for categorization is mediated by perceptual richness of information.

Several researches have been performed in various domains of knowledge about learning differences between learners regarded as experts and those regarded as novices. In some previous researches, we have investigated the learning, area of interest of researchers involved with cognitive science and computer science (AbLi96, Lima96, Po&col02 and Ca&col02).

In [AbLi96], for example, we conducted an experiment to examine characteristics related to cognitive gains in problem solving and the criterion to decide if a logical reasoning used in the solution of a specific problem could be used by similarity for other classes of problems. A more theoretical contribution concerning logic theory and its learning is in [Lima96].

[Po&col02] examines mental-representation strategies applied to solve contextual problems involving mathematical calculus: the interest is centered on formal procedures, algorithms, and strategies that could be used by three groups of peoples: with specific mathematical knowledge (*the expert group*); without this knowledge (*the control group*); and without this specific knowledge but acquainted with the designed problem context (*the familiar group*).

[Ca&col02] investigates the human reasoning applied to the mathematical problem-resolution process: the approach is based on two main settings: *a.* the investigation of mental processes involved in the human reasoning applied to problem resolution; *b.* the analysis of differences in the categorization and resolution of mathematical problems by beginners and specialists

We are actually developing a new experiment involving the teaching of computational logic by a playful approach (Socratic situation involving logical reasoning). This experiment aims to verify cognitive gains in two learners groups: experts and novices.

By examining the logical sequenced steps done to solve a logical entertainment we intent to detect criteria of utilization of reasoning by absurd or probabilistic reasoning by these groups. The extended idea concerns in fact the identification of cognitive contexts able to improve rather the use of probabilistic reasoning than reasoning by absurd and vice-versa. Of course, in our experiment, it is assumed incontestably that experts solve complex problems considerably faster and more accurately than novices do. Those differences are commonplaces of everyday experience, yet only recently have we begun to understand what the expert does differently from the novice to account for this superiority. Nevertheless, some initial results of our investigation could be applied to the learning of computational logic. These results could be applied in an elaboration of ideal pedagogical guidelines in order to facilitate the utilization of a more appropriate kind of reasoning to solve a particular Socratic problem.

Children's developing ability to create external representations: Separating *what* information is included from *how* the information is represented

Lara M. Triona (triona@cmu.edu) & David Klahr (klahr@cmu.edu)

Department of Psychology, Carnegie Mellon University
5000 Forbes Avenue, Pittsburgh, PA 15213 USA

Many areas of education focus on teaching children how to produce specific kinds of external notations. Although most children appreciate the usefulness of creating such representations by their eighth year, their ability to actually *create* useful external representations is highly variable and task specific until adolescence (Cohen, 1985; Karmiloff-Smith, 1979; Lee & Karmiloff-Smith, 1996; Eskritt & Lee, 2001). This variability could result from children's failure to realize *what* information needs to be included in a good representation, or it could result from their inability to figure out *how* to create such a representation, even if they know what to include in it. It is likely that these two difficulties interact such that, when children are deciding on their method of representation, they fail to verify that less salient pieces of information will be included. The current study is a first step in evaluating the contingencies between (1) *what* information is included, (2) *how* the information is represented, and (3) children's ability to create useful external representations.

We asked first and second grade children to create external representations that could be used by others to replicate a complex sequence of actions in a simple puzzle (Klahr, 1985). Children generated the sequence of moves themselves within a well-defined problem to assure they had sufficient understanding of the action sequence to be represented. The closed structure of the problem made it possible to define what specific information needed to be included in the external representation. In addition, we categorized the method of representation both for the overall organization of the notation and specific for each piece of information. In our analysis, we examined how the adequacy of the external representation (i.e., can another person use the notation to replicate the sequence of actions) relates to *what* information is included and *how* the information is represented.

Our analysis of children's external representations distinguishes among (a) references to the object to be moved, (b) the location to move the object, and (c) information about order of the moves. In order to categorize the overall organization of children's notations, we coded their notations as either linguistic or figural. The adequacy of representations was evaluated on a seven-point scale, with 1 denoting no relation between the notation and the task and 7 indicating that all information that was required to replicate the sequence was explicitly represented.

Of the three types of information included, children were more likely to refer to the objects and locations than to sequential order, $F(1, 25) = 21.8, p < .001$. This result is consistent with prior findings that suggested children had difficulty including explicit sequence information (Bolger &

Karmiloff-Smith, 1991; Lee & Karmiloff-Smith, 1996). Because information about move order was necessary for the notation to be rated as very adequate, the inclusion of sequential information in the notation was related to adequacy, $r = .82, p < .001$.

Similar to Lee & Karmiloff-Smith (1996), notational adequacy was associated with the overall organization of the notations, $F(1, 23) = 21.4, p < .001$, such that linguistic notations were more adequate than figural notations. The differential inclusion of information about sequence was highly related to notation type, $X^2(N = 24) = 12.2, p < .001$; all of the linguistic notations included information about sequence while a majority of the figural notations omitted this information. By categorizing the sequential information included as either explicit (i.e., words or numbers) or implicit (i.e., position on page such as top to bottom), we found that sequential information included in the linguistic notations was more likely to be implicit than in figural notations, $X^2(N = 13) = 5.3, p = .02$. However, we found an interaction between overall organization and method used to represent sequential information for notational adequacy, $F(1, 9) = 10.91, p = .01$, showing that figural notations with explicit sequential information did not have as high of an adequacy as linguistic notations.

The current study revealed a complex relationship between *what* information is included, *how* that information is represented, and notational adequacy. Future research should address why figural notations with explicit sequential information were not as adequate as linguistic notations.

What Does it Take to Pass the False Belief Task? An ACT-R Model

Lara M. Triona (triona@cmu.edu)

Amy M. Masnick (masnick@andrew.cmu.edu)

Department of Psychology, Carnegie Mellon University
5000 Forbes Avenue, Pittsburgh, PA 15213 USA

Bradley J. Morris (bjmorris@pitt.edu)

Learning Research and Development Center, University of Pittsburgh

The false belief task is used to assess whether children have a theory of mind (i.e., whether they know that other people can hold different beliefs). One version is the *unexpected contents* task (Perner, Leekam, & Wimmer, 1987), in which a child is shown a box (e.g., a crayon box) and its unexpected contents (e.g., candy). After the box is closed, a child is asked, "What did you think was in the box?" While children under 4 tend to answer "candy," older children respond correctly with "crayons." In order to explain this age effect, it is important to understand what is needed to pass the false belief task.

A computational model is one means of specifying the processes required. We designed an ACT-R (4.0; Anderson & Lebiere, 1998) model of the *minimal* processes needed to simulate performance on the false belief task. The model consists of five productions: two that respond to the two control questions, two that respond to the false belief question, and one that stops the model.

Our model includes three types of declarative knowledge: (1) *goals* contain the information presented in current question (e.g., a closed crayon box); (2) *general knowledge* provides relevant prior knowledge (e.g., crayons are usually inside a crayon box); and (3) *objects* indicate object-specific information (e.g., there is candy in *this* crayon box).

The first two productions specify the processes by which children respond to control questions. The expected contents production accesses prior knowledge about those types of boxes and identifies the contents based on this general knowledge. The second production uses specific input about the contents of the package (e.g., candy in the crayon box) to update the object-specific knowledge.

A correct response to the false belief question requires only a modification of the expected contents production: (1) identify the current question as a special case, (2) ignore the content knowledge about the *specific* box, and (3) refrain from changing object-specific knowledge based on prior general knowledge. Our model does not need to consider mental representations or beliefs in order to respond that crayons would be expected in a crayon box despite knowing there is candy inside the crayon box.

If a child fails to recognize the false belief question as a special kind of question, we expect she will simply report the actual contents of the box. The final production stops the model after responding to the false belief question.

When the model is run, each of the control questions match only one production; thus the model always responds

correctly. However, when the false belief question is posed, the model matches both the modified expected contents production and the report knowledge production. The developmental pattern in responses can be modeled by hypothesizing that the older children have had further experience with these special questions while the younger children have not. We modeled this by manipulating the parameter q – the probability that the production would achieve the goal. The pattern of results, shown in Figure 1, is similar to the pattern in children's responses. The model predicts that the reaction time for the correct response will be 500 milliseconds longer than an incorrect response.

Data from Model

Figure 1: Data from model showing % of runs that pass the false belief question as the difference in q varies from report knowledge production being more successful to the modified expected contents being more successful.

The current model only requires distinguishing questions that require reporting current knowledge from ones that require ignoring current knowledge. Because Wellman, Cross & Watson's (2001) meta-analysis found the developmental pattern of results for different versions of the false belief task was robust, it is likely that the current model can be generalized to other variations. We consider the current model a first step in specifying alternative explanations for false belief performance. This use of computational modeling can be productive in refining our understanding of the development of children's theory of mind into a more specified, and therefore testable, theory.

The Grounding of Symbols in Affordances

William H. Vidal

Scientific and Philosophical Studies of the Mind Program

Franklin and Marshall College

Lancaster, PA 17604

Wh_vidal@fandm.edu

Affordances vs. Experience

In the past two decades, the development of artificial intelligence has received thorough criticism from many philosophers. In his paper, *The Symbol Grounding Problem* (1990), Harnad attempts to prove A.I. systems' inaptitude to ground computational symbols in experience. To determine whether experience is the only criteria for grounding, a non-representationalist framework to artificial systems must be applied. This paper is an attempt to demonstrate the ability of artificial systems to ground their symbols in the potential activity afforded by their environment. To illustrate the grounding of symbols in affordances the analysis is presented in terms of Marr's three descriptive levels (Marr, 1983). Within the computational level, I present an ecological model of perception, as well as, how the behavior of an A.I. system is intelligible in terms of affordances. The placement of an A.I. system's behavior within the broader context of its environment widens the potential for grounding and draws the focus away from inner formal-symbol operations. Following the establishment of the environment's relevancy in A.I. systems' perceptual mechanism is an examination of the representational level. The program, at the representational level, represents the bridge between a system's ecological perceptual mechanism and the implementation of stimulus information. I conclude the analysis with the implementation layer's implications on which symbols need grounding and the causal link between the reception of stimulus information and motor commands.

The symbol Grounding Problem

The problem theoretically arises because the symbols in an A.I. system's representation layer are manipulated formally according to preset programmed rules and do not have any causal connections with the exterior world. In other words, the symbol grounding problem highlights the lack of connectedness between the symbols within the programmed layer of an A.I. system and the exterior environment. Whether one is trying to prove A.I. systems can have intentionality, develop a potential humanoid, or examine the replication of human processes through artificial intelligence, the symbol grounding problem poses a barrier. How can

one potentially make a machine that has meaningful thoughts, if its symbols are detached from any form of reality? According to Harnad, human mental symbols are grounded in our daily interactions with the exterior world. The association of symbols with memories leads Harnad to equate symbol grounding's constitutive element to experience and memories. (Harnad, 1990)

An Ecological Model

Within the bounds of his analysis, Harnad forwards valid criticisms of A.I. systems. Indeed, from a program layer investigation and a focus on internal abstract computation, A.I. systems do not have any connections with the exterior world. However, one is not claiming that a system's variables and design do not originate from a programmer and a system's general concept is the realization of a programmer's abstractions. These facts simply entail that the construction of an A.I. system is initially based on a designer's abstractions. Although the behavioral and program layer are the components we perceive and control, a grounding mechanism's processes reside within the implementation layer. An affordance structured analysis grounds an A.I. system's symbols by appealing to stimulus information, as opposed to the traditionalist appeal to causal energy connections. More precisely, the theory of affordances and direct perception enables a system to implement behavioral modifications through opportunities for actions specified in optic arrays. An alternate grounding mechanism must fulfill the three central tenets of symbol grounding theory: meaningful perception, purposeful action, and environment dependent symbols. Direct perception and Gibson's ecological approach forwards a dynamic model of action grounded in affordances that satisfies these three criteria. The symbol grounding problem is perspective dependent and is in nature, only a theoretical conflict.

Flexible use of prospective and retrospective memories

Horatiu Voicu (hv2@duke.edu)

Department of Psychological and Brain Sciences, 9 Flowers Dr
Durham, NC 27708 USA

Experimental data show that when animals are interrupted while executing a task, they optimize the use of prospective memory and retrospective memory in order to improve the performance of the task. This work describes a computational model of information retrieval from prospective and retrospective memories. The model includes a mechanism of memory load optimization that selects which memory participates in the decision making process. Computer simulations show that the model produces behavior similar to that found in rats and pigeons. Preliminary experimental results concerning memory load optimization in humans show a similar behavioral pattern.

Imagine that you go to the grocery store to buy 12 items for a special recipe you want to prepare. While you gather the items in your cart you meet a friend that asks you to help jumpstart her car because she has a discharged battery. After you help your friend you return to the store. Because you already spent too much time with your friend and your cart is located far away from the entry point of the store, you decide to take a new cart and pick up the remaining groceries. Then, you go to the location of the first cart that you used and notice that you have the complete list of groceries. What are the variables that influenced your behavior? Two important variables are the amount of time you spent with your friend and the number of groceries gathered until the point of interruption. Other factors are the degree of familiarity with the grocery store and the 12 items you intended to buy. Then, an important question is whether the number of groceries gathered until the point of interruption and the duration of time spent with your friend have an influence on holding a complete list of groceries (no duplicates or missing items) at the time you reach the first cart.

Answers to similar questions have been provided in studies with animals. For example, Cook et al. (1985) designed a study to find what type of encoding rats use to solve a 12 arm radial maze. Subjects were trained to find food in the maze so that they have an internal representation of the maze. At the beginning of each trial all the arms of the maze are baited. Rats are placed in the maze and allowed to explore 2, 4, 6, 8, or 10 arms before they are removed from the maze. After a certain amount of time has elapsed they are placed back in the maze and allowed to explore the maze until all food is collected. The number of errors committed by the subjects during one trial measures their performance. The results show that subjects can shift their coding strategy to optimize their memory load. An interruption after the 6th arm produces an error larger than that generated by an interruption close to either the beginning or ending of the task. Similar results have been obtained with pigeons

(Zentall et al., 1990) in an analog task of the radial arm maze.

This work introduces a computational model that describes how animals can achieve memory load optimization. The model contains a retrospective memory, a prospective memory and a mechanism for deciding which memory is used for producing action.

Figure 1 shows the performance of the model when the point of interruption and the delay are varied. Figure 2 shows experimental data for interruptions of 15 and 60 minutes. These data are similar to those presented in figure 1 (see delay 8 and 25). Both theoretical and experimental studies suggest that while short delays affect only the performance interrupted halfway, long delays affect any performance interrupted after the 6th arm.

The computer simulations suggest that prospective memory decays faster than retrospective memory. This might happen because prospective memory is not used as often as retrospective memory. Prospective memory can be used only when a complete representation of the task exists in memory.

Figure 1. Performance of the model when exploration is interrupted after the 2nd, 6th and the 10th arm while the delay increases.

Figure 2. Experimental data that show the performance of rats when delay is 15 minutes (A) and 60 minutes (B).

Motivational Patterns During Hypermedia Learning

Regina Vollmeyer (vollmeyer@rz.uni-potsdam.de)

Falko Rheinberg (rheinberg@rz.uni-potsdam.de)

Institut für Psychologie, Universität Potsdam, Postfach 601553
14415 Potsdam, Germany

Bruce D. Burns (burnsbr@pilot.msu.edu)

Department of Psychology, Michigan State University
East Lansing, MI 48824-1117

Our aim was to test Vollmeyer and Rheinberg's cognitive-motivational process model (2000) in the context of learning a hypermedia program. The model assumes that initial motivation affects learning through the mediating variables *motivational state* during learning and *strategy* used for learning. Initial motivation contains four factors: *probability of success*, i.e., learners take into account their ability and the perceived difficulty of the task; *anxiety*, i.e., learners think about failing the task; *challenge*, i.e., whether learners accept the situation as an achievement situation; and *interest*, i.e., whether the topic of the learning material is important.

Method

The hypermedia program described the outbreak of World War I (Vollmeyer & Burns, 2002) on 51 pages. The 42 participants read the instructions saying that after about 25 minutes of learning they will answer a questionnaire. Before starting they answered the QCM (Questionnaire of Current Motivation; Rheinberg, Vollmeyer, & Burns, 2001) measuring anxiety, probability of success, interest, and challenge. When working with the program we measured two mediating variables: (1) the motivational state (three items e.g., "The task is fun"), and (2) strategy as time per page. The dependent variable was knowledge assessed with 34 questions. To take speed as well as accuracy into account we calculated knowledge as the product of correct answers in the knowledge test and number of pages looked at.

Results and Interpretation

The four factors of initial motivation have some intercorrelation (Rheinberg et al., 2001), so we looked for common patterns in initial motivation through a hierarchical cluster analysis. We found 2 groups: In the first group interest and probability of success were significantly higher, in the second group anxiety and challenge (see Table 1). Thus we interpreted the first group as interested and believing in success (I/P), the second as challenged, but fearing failure (A/C). Table 1 shows how differently these two groups learned the program. The I/P-group had a higher motivational state during learning, they looked at more pages and thus spent less time per page. Knowledge, measured as the product of number of pages * correct answers, was also higher for the I/P-group.

Table 1: Means for I/P- ($n = 20$) and A/C-group ($n = 22$).

	I/P	A/C	<i>p</i>
interest	5.34	4.58	.013
probability of success	5.94	4.74	.001
challenge	4.18	4.69	.065
anxiety	1.54	3.35	.001
motivational state	5.60	4.46	.004
time per page	30.55	38.81	.013
number of pages	43.70	35.91	.008
correct answers	15.05	12.86	.082
number * correct answers	653.00	460.82	.002

To test if initial motivation affects learning through the motivational state and strategy we calculated regression analyses. First we found that initial motivation correlated with motivational state, $r = .44$, time per page, $r = -.38$, and knowledge, $r = .46$. The mediating variables also correlated with knowledge (motivational state: $r = .37$, time per page: $r = -.58$). However, in a regression analysis, in which the predictor (I/P-, A/C-group) is controlled, only time per page is significant, $\beta = -.46$, $t = 3.52$, $p = 0.001$. In conclusion, we found that initial motivation affected learning only via strategy: More anxious and challenged learners spent more time per page but they learned less of the page's content compared to success-oriented and interested learners.

Preschool Children's Use of Auditory Information in Drawing Inferences about Animal Kinds

Winnie H.K. Wai (h9910031@hkusua.hku.hk)

Benise S.K. Mak (benise@hku.hk)

Department of Psychology, The University of Hong Kong,
Pokfulam Road, Hong Kong, PR China

Infants are born with five senses: sight, hearing, taste, smell and touch, through which they come to understand the world around them and interact with the environment effectively. However, the role of visual information in early conceptual development has been stressed. In this paper, we would argue that auditory information should also play a part. For instance, the sound of an animal can be one of the essential cues for us to determine what the animal is. This study, therefore, was an attempt to examine the extent to which preschool children use auditory information in drawing inductive inferences about animals.

In a recent study by Wong (dissertation), 4-year-old children's use of auditory and visual information has been compared. They were found to be more likely to draw inferences about natural kinds based on the similarity of auditory information than on shape similarity. The importance of auditory information has been shown.

However, some would argue against the importance of perceptual information no matter whether it is visual or auditory. A series of studies by Gelman et al. (e.g., Gelman & Coley, 1990) have shown that children as young as 3 years of age were able to go beyond perceptual cues and use conceptual information, such as category labels, to make judgments. They tended to rely more on labels than on perceptual appearance to draw inferences about animals.

Despite of these findings, the role of category labels has been questioned. A study by Mak, Vera and Lo (under preparation) has shown that young children's use of labels seems to be rather limited. Preschool children tended to use motion information more often than category labels to make categorical judgments.

Following this line of argument together with the evidence that infants are not only sensitive to sound but also show good ability in sound detection, discrimination and localization (e.g., Leventhal & Lipsitt, 1964; Wormith, Pankhurst, & Moffitt, 1975), it is reasonable to believe that preschool children would be more likely to use the sound of animals than category labels to draw inductive inferences.

The present study was a 2 (similar & different sound) \times 2 (similar & different label)

between-subject factorial design. Two hundred and forty 4-year-old children participated. In the experiment, each child was tested individually. Children were presented with 2 pairs of animal stimuli ("cat" and "dog"), one pair at a time (a target and a test animals which shared similar appearance). The children were first taught a new property about the target and were then asked to infer if the property was also true for the test animal.

Results provide supports for our hypothesis, showing that 4-year-olds tended to use auditory information significantly more often than verbal labels to draw inductive inferences about the animal stimuli. This finding is consistent with those in Mak et al.'s study, suggesting that the role of category labels may not be as important as Gelman et al. have suggested and that of auditory information cannot be ignored.

Although children's use of perceptual and conceptual information has been compared in this study, we are not suggesting that they play distinct roles in children's conceptual development. On the contrary, we do believe that information of shape, sound and labels interact to guide children's categorical judgment. This, however, remains to be determined in future studies.

If Only I Had Acted Differently: Reasons and Actions in Counterfactual Thinking

Clare R. Walsh (cwalsh@tcd.ie)

and Ruth M.J. Byrne (rmbyrne@tcd.ie)

Psychology Department, University of Dublin, Trinity College, Dublin 2, Ireland

Counterfactual Thinking

Suppose an action of yours leads to a bad outcome. You are plagued by thoughts of 'if only I hadn't acted'. But suppose you are reminded of a very good reason why you acted. Will the reason diminish your tendency to think 'if only' about your action? Our aim is to report experimental results on how the *reasons* for actions can influence 'if only' thoughts.

Generating counterfactual thoughts about what might have been may be central and pervasive in human cognition (e.g., Byrne & McEleney, 2000). Counterfactual thoughts follow certain regularities. Most importantly, for our purposes, people think 'if only' about controllable events (e.g., stopping for a beer) rather than uncontrollable ones (e.g., sheep crossing the road) (Giroto, Legrenzi & Rizzo, 1991; McCloy & Byrne, 2000). The focus on controllable actions has been demonstrated repeatedly in real life as well as laboratory studies. The ability to imagine that a person could have acted differently may be central to our concepts of freedom and responsibility and may underlie emotions such as guilt and regret.

Why do people think 'if only' about controllable actions? The answer may be that they are perceived to be independent of external causes (Giroto et al., 1991). But most actions depend on a *reason*. We examine how reasons for acting can influence 'if only' thoughts.

There are many different sorts of reasons (Walsh & Byrne, 2002). Reasoners may view some reasons as necessary, and may imagine that without the reason the action would not have occurred. Other reasons may be viewed as non-necessary and reasoners may imagine alternative reasons for acting. We suggest necessary reasons are generally *enduring*, oriented towards longer term plans whereas non-necessary reasons tend to be *immediate*, satisfying current desires and short-term goals. We expected that reasoners' would generate fewer 'if only' thoughts about actions for which there were necessary reasons compared to non-necessary reasons or no reason.

Imagining Counterfactual Alternatives

In one experiment, we constructed three versions of a scenario about an individual, Tom, who is delayed by several events on his way home from work, only to find he is too late to save his dying wife. In one version the action (going to the gym) was preceded by a non-necessary reason, an immediate desire to act 'for its own sake' (Tom really likes to go to the gym'); in a second, the action was preceded by a necessary reason, an enduring long-term plan

('Tom is trying hard to lose weight'), and in the third version no reason was given.

We assigned 194 students to one of the three groups. They listed four completions for the following counterfactual thought:

As commonly happens in such situations, Tom often thought, "if only..."

The results showed that a necessary reason reduced participants' tendency to think 'if only he hadn't acted' (75%) compared to a non-necessary reason (89%, $\chi^2 = 3.86$, $p < .025$), and compared to no reason (88%, $\chi^2 = 3.32$, $p = .03$). A necessary reason shifts some 'if only' thoughts from the action to the reason instead. The possibility in which the reason does not occur and the action occurs anyway is ruled out and so a counterfactual can be generated of the form, "if only the reason had not happened, the action would not have happened." In contrast, for non-necessary reasons there is the possibility that the reason does not occur and the action occurs anyway and so a counterfactual cannot be generated of the form, "if only the reason had not happened, the action would not have happened."

The focus of counterfactual thoughts on controllable actions may arise in part because controllable actions seem to be independent of any external constraint. Once such constraints are made apparent, in the guise of the provision of reasons for acting, the tendency to think 'if only' about controllable actions is reduced.

1. Background

Enthusiastic educators digitize different sorts of learning materials in the hope of enhancing learning outcome. The learning outcomes from this trend, however, remain inconclusive because detailed evaluation is often lacking.

One difference between the traditional printed medium and the digital medium is the arrangement of presentation of the concepts to be learnt. Digital medium allows the concepts to be arranged in a networked structure with the aid of hyperlinks which is not possible in traditional printed medium. The advantage of networked structures lies in encouraging the active exploration of information in the absence of any predefined structure. This encourages an active knowledge construction process, which is crucial in learning. A concomitant disadvantage is that learners may get easily lost in the network (Dix, Finlay, Abowd & Beale, 1998).

The digital medium may therefore complement the strengths of problem-based learning pedagogy, as they share the same objective in encouraging the learners to explore. The disadvantage of the digital medium may on the other hand be overcome through providing learners with browsing objectives, such as instructions to solve particular structured problems within a PBL learning framework.

2. Method and Results

To assess the interaction effects of problem-based learning and digital medium, techniques in learning outcomes assessment were further explored. These evaluated the learners' semantic differentiation with the help of multidimensional scaling. Chi, Feltovich and Glaser (1981) argued that experience level determines the differentiation of a problem. A number of other researchers have also suggested that expertise affects concept differentiation, experts tending to differentiate concepts more finely and more systematically (c.f. Fisher, 2000).

2.1 Construction of Expert Model

A group of research postgraduate students with biological psychology background was asked to make pair-wise difference comparisons on some biological psychology terms, which constitute the dissimilarity matrices. ALSCAL (Alternating Least squares SCALing) solutions of them was constructed, and regarded as the experts' model.

2.2 Pedagogy and medium interaction effect

A 2x2, medium (digital, printed) x pedagogy (directed learning, problem-based learning), research design was run in an authentic biological psychology learning environment. Dissimilarity matrices data were collected after the learning sessions. Preliminary data analysis suggested that

multidimensional scaling solutions were problematical in terms of the groups, because of the large variance within group. Individual ALSCAL solutions were, therefore, constructed, from which parameters were derived for further analysis.

2.2.1 Tuncker's Congruence Coefficient

Tuncker's congruence coefficients between individuals' and the experts' dissimilarity matrices were calculated based on the first stage results. A 2x2 ANOVA (pedagogy x medium) showed that there is a significant pedagogy main effect ($F = 17.414$, $p < 0.01$). The knowledge differentiation criteria by the individual in the directed learning group are more similar to the experts' group model than to the problem-based learning group.

2.2.2 Further analysis

Further analyses using parameters from a cluster analysis and property vector fitting revealed no significant difference between groups.

3. Discussion

The results indicated that the effect of medium shift is not as dramatic as the effect of pedagogy application. Educators should consider putting more effort into implementing useful pedagogy rather than digitizing learning materials alone.

The pedagogies investigated in this study, through directed learning, which mimics the nature of traditional teaching, and problem-based learning, yield different semantic knowledge structures. This mirrors the objective of problem-based learning, in that it leads the learners to construct their own understanding. The individual semantic models that are derived as outcomes from this process are, therefore, less congruent with those of the experts. Whether this is beneficial or not depends on the teaching objective. Finally, this research only explores one area of digital medium based instruction. The effects of more sophisticated digital functions, for example animation, intelligent tutor and online-collaboration, should be further explored.

The Neural Instantiation of Number

John W. Whalen (whalen@udel.edu)

Frank Morelli (fmorelli@udel.edu)

Department of Psychology, University of Delaware
Newark, DE 19716 USA

Introduction

Fundamental to calculation and arithmetic competency is the ability to abstractly represent numerical quantity. While much is known about the psychophysics of human quantity representation, little is known about the neural instantiation of this key ability. Through ERP (event-related potentials), we characterize the nature of multidigit numerical representations. Dehaene (1996) revealed that bilateral regions of parietal cortex are involved in judging the largest of single digit numbers (1,4,6, and 9) from the number 5. Our research replicates his findings and also considers the nature of the neural representation of the magnitudes themselves. Preliminary studies have revealed systematic variations in ERP signature in response to the presentation of small numerical quantities (range: 1 – 16). This activation is localized to bilateral inferior parietal regions and occurs 220 ms after stimulus onset (Whalen, West, & Cook, 2002). The present work investigates the neural representation of larger quantities, and the mapping of multidigit numerals to neural quantity representations.

Methodology

Participants were shown Arabic digits ranging from 0 to 99. Stimuli were randomized and presented individually for 500 ms. Because Arabic numerals are known to automatically elicit representations of numerical magnitude (Lefevre et al., 1988; Naccache & Dehaene, 2001), no response was required of participants. Participants were also periodically asked to compare the relative numerical magnitude of two sequentially presented numbers (participants judged whether the second number in the pair was "smaller" or "larger" than the first). Event related potentials were recorded using a 128 channel EGI (Electrical Geodesics, Inc.) Sensor Net. ERPs were collected for each tens quantity (e.g, 3 of 34), units quantity (e.g, 4 of 34), and overall magnitude (e.g., 34) for 250 ms prior to stimulus onset to 500 ms post onset.

Results

Using single and double-digit Arabic numerals ranging from 0 to 99, we discovered functionally distinct neural representations for the individual numerals that compose a multidigit number (e.g., the "3" and "4" of the multidigit numeral "34") and for overall numerical magnitude. Regression analysis over 20 ms intervals at each electrode site revealed systematic linear variation in neural voltages relative to the numeral presented. This included distinct representations for both the tens and units quantities, and the

overall magnitude. Overall magnitude was represented bilaterally in inferior parietal regions, while tens and units representations were localized to the right superior parietal gyrus. While the ERP signature for each quantity was localized to unique regions of parietal cortex, the onset of the representations were nearly simultaneous, commencing approximately 220 ms after presentation of the numeral. The linear changes in ERP signatures relative to the magnitude presented suggests that number is represented linearly in parietal cortex, a finding consistent with studies of quantity representations in non-humans (Gallistel & Gelman, 2000).

Partial Analogical Transfer in Problem Solving: Roles of Centrality and Order

Tsunhin J. Wong (thjwong@hkusua.hku.hk)

Albert W. L. Chau (awlchau@hkucc.hku.hk)

Department of Psychology, University of Hong Kong
Pokfulam Road, Hong Kong

Antonietti (1991) first presented the idea of partial analogies in solving an ill-defined problem. Prior to that, studies looking into the role of analogies in problem solving used complete analogies. Antonietti concluded that partial analogies helped problem solving only when all the cues were present and presented in the correct order.

The conditions for partial analogy to work as identified by Antonietti seem to be overly stringent. Partial analogy should be effective in most situations as most analogical cues available in daily life are partial in nature. This study therefore looks into the role of analogical transfer of partial analogies.

Our study differs from Antonietti (1991) in a few ways. First, as it is logical to assume that some analogical cues are more crucial than the others, the notion of centrality of an analogy was examined. Second, we also revisited if analogical cues have to be presented in the exact order in order to be effective. Finally, we presented the partial analogies as problems for participants to solve rather than disguised them as arithmetic problems.

Method

Forty undergraduates at the University of Hong Kong participated in the experiment as part of a course requirement. None of them had been exposed to the problems used in the study.

Every participant completed the experiment on a computer. The problems were written in Flash with both texts and diagrams.

Procedure

Two types of problems were used in the experiment. The analogy problems were concerned about how to direct water to a target location. They were used to prime participants to use the two strategies which are necessary for solving the target problems: divergence which is dividing the flow to avoid overload and convergence which is pulling together the divided flows to achieve the intensity needed. The target problems were the Fortress problem and Duncker's radiation problem. The first problem deals with how to organize soldiers to conquer and castle while the other deals with how to use X-ray to destroy a tumor.

Each participant was first told some basic concepts subjects in fluid dynamics. S/he then proceeded to solve one of the four versions of the analogy problem depending on the experimental condition to which s/he was assigned: i) *partial analogies* presented in the *correct* order (divergence then convergence), ii) *partial analogies* presented in the *reverse* order (convergence then divergence), iii) *complete* analogy; and iv) *unrelated* analogy. Finally the participant was asked to solve the two target problems. If s/he could not solve a problem within 5 minutes, s/he was then told that the

problems they had tackled earlier might help them. A total of 10 minutes were allowed to solve each problem.

Results and Discussion

43.9% of the subjects solved the Duncker's problem without being prompted to use the previous problems, with the highest in the *partial-correct* condition (81.8%) and the lowest in the *unrelated* condition (20%).

Solving the Fortress problem in the *unrelated* condition required more time than in all the other conditions. Time required to solve the Duncker's problem was in the decreasing order of: *partial-correct*, *partial-reverse*, *complete*, and *unrelated*. Besides, the *partial-correct* condition required the least prompting for using the partial analogy condition.

Contrary to Antonietti's study, participants in the *partial-reverse* condition were able to solve the target problems spontaneously. In other words, exposure to partial analogies is sufficient for priming to occur though the exact temporal order can provide additional facilitation. Second, it was also found that partial analogies were more effective than *complete* analogy in priming the participant to solve the target problem. This is possibly due to the complexity involved in solving the complete analogy problem. Third, the present findings suggested that convergence plays a more central role in analogical transfer. This is in line with Pedone, et al (2001) who found that convergence alone was sufficient to trigger spontaneous analogical transfer. The second and third findings together suggested that convergence is the more central partial analogy. Only it should be presented to achieve the greatest priming or facilitatory effect in problem solving. Presenting a less useful partial analogy (divergence) lowers instead of enhances the transfer in problem solving performance. This may be explained by introducing a weight system in the branches of the structural mapping theory (Gentner, 1983) or constraints in the multiconstraint theory (Holyoak & Thagard, 1980).

Mental metalogic and its initial empirical justifications: The case of reasoning with quantifiers and monadic predicates

Yingrui Yang and Selmer Bringsjord

yangyri@rpi.edu • selmer@rpi.edu

Department of Cognitive Sciences

Rensselaer Polytechnic Institute, Troy, NY 12180 USA

In psychology of human deductive reasoning, mental logic theory claims that people reason by applying inference schemas (e.g., Braine & O'Brien, 1998; Rips, 1994), and mental models theory claims that people reason by constructing mental models (e.g., Johnson-Laird and Byrne, 1991). There is a great deal of empirical evidence supporting each theory. The authors have proposed a mental metalogic theory (Yang & Bringsjord, 2001) studying the interactions between applying inference schemas and constructing mental models based on the current theories of mental logic and mental models. We report a set of experiments designed to examine possible interactions of this kind. Mental metalogic suggests ways of modeling reasoning strategies.

Our strategy for constructing experimental problems was to integrate one problem type used in mental logic research (Yang, et al. 1998) and another problem type used in mental model research (Yang & Johnson-Laird, 2000). Below is a resulting sample problem used the experiment.

The premises given below are either all true or all false:

All the beads are wooden or metal.

The wooden beads are red.

The metal beads are green.

The square beads are not red.

Is possible that the square beads are green?

This new problem type can be used to manipulate two independent variables. The first independent variable is about the set of premises. For a given problem, it can have the set of original premises, or the denials of these premises. The second independent variable is how a question is presented. It can take the form, "Is it possible that ..." or "Does it necessarily follow that ...". Thus, by manipulating these two independent variables, four types for a given problem are produced. The first experiment used a 2x2 between-subjects design to manipulate two independent variables in four conditions according to the 4 problem types explained above. 18 original multi-step problems similar to the example above were carefully selected from Yang, et al. Their task was to choose among the given responses (i.e., Yes, No, or Can't tell). The mean accuracy for the original/necessity problems was 45.5%, for the original/possibility

problems 91%, for the denials/necessity problems 83%, and for the denials/possibility problems 60%. (N=40 for each problem type). The results are clear-cut. For the problems using original premises, the problem type of possibility was evaluated significantly more accurately than the problem type of necessity (Mann-Whitney $U_z = 5.17$, $p < .001$). For the problems using the denials of the original premises, the problem type of necessity was evaluated significantly more accurately than the problem type of possibility (Mann-Whitney $U_z = 5.14$, $p < .001$). In addition, there was a reliable interaction. The difference between problem types of necessity and possibility for the problems using original premises was greater than for the problems using the denials of the original premises (Mann-Whitney $U = 44$, $p < 0.01$). The similar results were obtained from a second set of experiments using dyadic predicate problems parallel to the monadic predicate problems used in the first experiment. A 2x2 within-subjects design was used (N=140, individually tested). This time the latency data were also collected, and the results showed that an answer took significantly longer time when two cases (both "all true" and "all false" situations) needed to be considered than when only one case (i.e., "all the premises are true") needed to be considered. For the problems with original premises and necessity questions, 55% subjects answered yes, which was an illusion because they failed to consider the "all false" case. But they could apply inference schemas in the local situation of "all true". However, another fairly large portion of participants (45%) responded "No" to the problems of this type, and would have needed to consider the "all-false" case, which took longer time. In this local situation, there are no inference schemas currently available to deal with the denials of the original premises, and reasoners may likely construct mental models.

There are long-standing controversies between mental logic and mental model theories, as well as other emerging controversies between the mental logic/model paradigm, mental metalogic, and other approaches in reasoning. Deduction is core to human cognition. These issues deserve open discussions and debates, which have been the ways for different theories to grow in this field.

"If" is easier than "or" in the GRE

Yingrui Yang (yangyri@rpi.edu)

Department of Cognitive Sciences, Rensselaer Polytechnic Institute
Carnegie Hall, Troy, NY 12180 USA

Philip N. Johnson-Laird (phil@princeton.edu)

Psychology Department, Princeton University
Princeton, NJ 08544 USA

In logic, a conditional, such as: "If the trend continues then a decline will occur" is equivalent to a disjunction: "Either the trend stops, i.e., doesn't continue, or a decline will occur". Both assertions are compatible with the following three possibilities, where " \neg " denotes negation:

Trend	Decline
\neg Trend	Decline
\neg Trend	\neg Decline

The equivalence may break down as a result of the specific content or context of assertions (Johnson-Laird and Byrne, 2002). But, where the two assertions are equivalent, the conditional has the mental models:

Trend	Decline
-------	---------

in which the first model represents the possibility in which the antecedent is true, and the second wholly implicit model represents the possibilities in which the consequent is false. The disjunction has the mental models:

\neg Trend	Decline
\neg Trend	Decline

It follows that reasoning should be easier with the conditional than with the disjunction.

We conducted three experiments to test this prediction using "logical reasoning" problems from the Graduate Record Examination (the GRE, devised by Educational Testing Services, Princeton. In Experiment 1, 20 participants carried out either a conditional version or a disjunctive version of 8 GRE problems, e.g.: the conditional version:

Because the number of surgeons is growing faster than the number of operations and because noninvasive medical therapies are increasingly replacing surgery, the average annual number of operations per surgeon has fallen by one-fourth in recent years. It can be concluded that, if these trends continue, a dangerous decline in the level of surgical skill will occur.

The argument is based on which of the following assumptions?

(A) Surgeons now spend a large percentage of their time performing noninvasive medical procedures.

(B) A surgeon's skill cannot be properly maintained unless the surgeon performs operations with a certain minimum frequency.

Option (B) is the correct answer. The disjunctive version included instead the following final assertion:

It can be concluded that, either these trends stop, or a dangerous decline in the level of surgical skill will occur. The participants had to select the correct response from the pair of assertions, which were the correct conclusion and the most frequently chosen foil (according to ETS). The accuracy of responses did not differ, but the participants were reliably faster to solve the conditional problems (mean 1.76 min.) than the disjunctive problems (mean 2.06 min.).

Experiment 2 was a replication but in which the two response options were conditionals (for the conditional problems) and disjunctions (for the disjunctive problems). The participants were reliably more accurate and faster with the conditional problems (73% correct, 0.8 min.) than with the disjunctive problems (61% correct, 1.17 minutes). The use of a sentence containing a given connective in both the text and the two response options evidently amplified the difference between conditionals and disjunctions.

Experiment 3 used conditional and disjunctive texts with conditional and disjunctive response options in all four combinations. The results showed that the nature of the response options was decisive. The 40 participants were faster and more accurate with problems that had conditional responses than with problems that had disjunctive response options.

We conclude that the model theory's predictions about the different representations of conditionals and disjunctions extend to realistic problems based on the GRE. Theories based on formal rules of inference (e.g., Braine and O'Brien, 1998; Rips, 1994) make no predictions about this difference. The research was a part of the project, eWriter, which was supported by a grant from ETS and the GRE Board to S. Bringsjor, Y. Yang, P.N. Johnson-Laird, and M. Bauer.

A Computerized Lexical Database of Cantonese

Michael C. W. YIP

School of Arts & Social Sciences, The Open University of Hong Kong

myip@ouhk.edu.hk

Introduction

Lexical databases are now available for many languages over the world, for example, CELEX and Euro WordNet. However, there are not any comparable data of this kind for Cantonese. The necessity of this database cannot be underestimated since not much progress on the Chinese (Cantonese) psycholinguistic research can be made without the succor of these kinds of precise lexical information (Li & Yip, 1996, 1998; Yip, 2000). This project aims at making a large-scale collection of digital tape recordings of Cantonese speech and establishing an archive of Cantonese texts based on transcriptions of these recordings. A corpus of Cantonese syllables and words together with other polysyllabic Chinese expressions will be constructed. In the database, much useful lexical information can be generated: for example, spoken word frequency, frequency information of phoneme occurrence and phoneme co-occurrences, speech errors. In this project, a large-scale lexical database of Cantonese will be established in two phases. In the first phase, the target is to have a database of 300,000 Cantonese words. In the second phase, the target will be up to one million Cantonese words. It is hoped that the subsequent psycholinguistics research in the Chinese language can benefit from this computerized lexical database.

Main Objectives

Three main objectives of the project here are:

- (1) Generation of relevant lexical information of Cantonese Chinese speech: the database can generate such kinds of useful lexical information for psycholinguistic research as (a) the frequency information of spoken Cantonese word (cf. Yip, 2001); (b) the probabilistic phonotactic information of Cantonese speech (Yip, 2000)
- (2) Determination of the processing and production unit of Cantonese speech: from the data of speech error collected in the database, we can closely monitor if the speech error of Cantonese involved a whole syllable replacement or other sub-syllabic components interchanging (cf. Chen, 2000), and then inferred to the functional units of Cantonese speech (Chen & Yip, 2001; Yip, Song, & Chen 1999)
- (3) Estimation of the code-switched situation in Hong Kong: from the database, we can estimate the size of code-switching and types of code-switchers in the bilingual situation of Hong Kong (Chan, 1992)

Methodology

This project is designed to construct a computerized lexical database of Cantonese. The database can be used to generate several different kinds of lexical information of Cantonese natural speech. It is based on the large-scale collection of digital tape recordings of natural Cantonese speech. Sources of the natural Cantonese speech include dialogues of Radio call-in programs (Chen, 2000), conversations of TV programs, casual

chatting among the students in canteen. Collecting the Cantonese speech from different sources of naturalistic settings guaranteed the ecological validity of the lexical information generated from the database. Because the data gathered to the database is entirely came from the real and natural cases which obviously are psychologically real as well as can reflect the lexical information embedded in our mental lexicon.

Expected Results

The result of this project will be summarized in a computerized lexical database of Cantonese that is significant to research as well as to language teaching and learning. In terms of research, we believe that a more solid rigorous set of lexical information of Cantonese speech can be derived and it can have a wide range of applications to linguistic as well as psycholinguistic researches, especially lexical research centering on spoken language processing. In terms of language pedagogy, it will provide empirical ground for designing the most appropriate language learning methods to students according to the patterns of the prominent processing and production units of native Cantonese speakers. Meanwhile, it will also provide useful information of the pervasive code-switching situation in Hong Kong that clearly confounded the traditional language teaching methods in Hong Kong education sector.

ANNUAL CONFERENCES OF THE COGNITIVE SCIENCE SOCIETY

Proceedings of the:

Twenty-Third	(2001)	\$180.00	\$55.00*
Twenty-Second	(2000)	\$150.00	\$65.00*
Twenty-First	(1999)	\$150.00	\$49.95*
Twentieth	(1998)	\$180.00	\$65.00*
Nineteenth	(1997)	\$180.00	\$65.00*
Eighteenth	(1996)	\$180.00	\$55.00*
Seventeenth	(1995)	\$180.00	\$55.00*
Sixteenth	(1994)	\$150.00	\$55.00*
Fifteenth	(1993)	\$150.00	\$49.95*
Fourteenth	(1992)	\$150.00	\$49.95*
Thirteenth	(1991)	\$150.00	\$49.95*
Twelfth	(1990)	\$150.00	\$49.95*
Eleventh	(1989)	\$150.00	\$49.95*
Tenth	(1988)	\$150.00	\$49.95*
Ninth	(1987)	\$150.00	\$49.95*
Eighth	(1986)	\$150.00	\$49.95*
Seventh	(1985)	\$150.00	\$49.95*
Sixth	(1984)	\$150.00	\$49.95*
Fifth	(1983)	\$125.00	\$24.95*
Fourth	(1982)	\$79.95	\$24.95*
Third	(1981)	\$100.00	\$24.95*

*Special Discount Prices. No further discounts apply.

Applies if payment accompanies order or for course adoption orders of 5 or more copies.

Please stop by the LEA booth at the Cognitive Science Society Meeting to peruse and/or purchase these volumes and receive valuable at-conference discounts on other relevant LEA titles.
